Phylum XXVI. Actinobacteria phyl. nov.

Michael Goodfellow

Ac.ti.no.bac.te′ri.a. Gr. n. *actis -inos* a ray, beam, N.L. n. *bacter* a rod; suff. *-ia* ending denoting phylum; N.L. pl. neut. n. *Actinobacteria* actinomycete bacteria with diverse morphologies.

This taxon is one of the major phyla in the domain *Bacteria*, as inferred from its branching pattern in the 16S rRNA gene tree (Garrity and Holt, 2001; Ludwig and Klenk, 2005) and taxon-specific 16S rRNA signatures (Zhi et al., 2009). The separation of the phylum from other bacterial taxa is supported by conserved indels in some proteins (e.g., cytochrome-*c* oxidase subunit 1, CTP synthase and glutamyl-tRNA synthase), by the presence of a large insert in 23S rRNA (Gao and Gupta, 2005; Gao et al., 2006) and by distinctive gene arrangements (Kunisawa, 2007). The nearest phylogenetic neighbor to the phylum is not clear (Ventura et al., 2007) though the *Firmicutes* are usually considered in this context. In this volume of the *Manual*, the phylum *Actinobacteria* encompasses five classes, 19 orders, 50 families, and 221 genera. However, many new taxa continue to be discovered so this listing is inevitably incomplete. The constituent classes are *Acidimicrobiia* class. nov., *Actinobacteria* (Stackebrandt et al., 1997), *Coriobacteriia* class. nov., *Rubrobacteria* class. nov., and *Thermoleophilia* class. nov.

Actinobacteria are Gram-stain-positive or Gram-stain-variable aerobes, facultative anaerobes or anaerobes, which have a rigid cell wall that contains muramic acid. Some contain wall teichoic acids. Most are chemo-organotrophs which grow at neutral pH, but some are acidophiles or alkalophiles. Others are halophiles and some are thermophiles. The phylum includes phenotypically diverse organisms which show diverse morphological properties that range from cocci to highly differentiated mycelia. Most are saprophytic, but some are pathogenic for plants and animals. The DNA G+C content ranges from just under 50 mol% (e.g., *Hoyosella* and *Tropheryma*) to over 70 mol% (e.g., *Frankia* and *Streptomyces*). Members of the taxon are widely distributed in aquatic and terrestrial habitats (Goodfellow and Williams, 1983; Jensen and Lauro, 2008; Stach and Bull, 2005; Williams et al., 1984).

Type order: **Actinomycetales** Buchanan 1917, 162^{AL} emend. Zhi, Li and Stackebrandt 2009, 594.

Taxonomic comments

The class *Actinobacteria* and constituent taxonomic ranks above the genus level were proposed by Stackebrandt et al. (1997) solely on the basis of 16S rRNA gene sequence-based groups and taxon-specific 16S rRNA gene sequences. This classification represented a step-change in the classification of actinomycetes above the genus level as it showed that previous classifications based on form and function were wanting as they did not reflect natural relationships. Comprehensive accounts of earlier classifications of actinobacteria are available (Cross and Goodfellow, 1973; Goodfellow and Williams, 1983; Stackebrandt and Schumann, 2006). In addition, the evolutionary history of the phylum has been traced by Ventura et al. (2007). At the genus level, good correlation has been found between the phylogenetic position of organisms and the discontinuous distribution of key chemical markers (Embley and Stackebrandt, 1994; Goodfellow, 1989; Goodfellow and Maldonado, 2006; Kroppenstedt and Goodfellow, 2006). The class *Actinobacteria* and constituent higher taxa have been updated by Zhi et al. (2009). In this volume, the actinobacteria have been assigned the rank of a phylum as the phylogenetic depth represented by the lineage corresponds to that of existing phyla (Garrity and Holt, 2001; Ludwig and Klenk, 2005).

Class I. **Actinobacteria** Stackebrandt, Rainey and Ward-Rainey 1997, 483

Michael Goodfellow

Ac.ti.no.bac.te′ri.a. Gr. n. *actis -inos* a ray, beam; N.L. n. *bacter* a rod; suff. *-ia* ending denoting a class; N.L. pl. neut. n. *Actinobacteria* actinomycete bacteria with diverse morphologies.

Upon publication of the class *Actinobacteria*, a type order was not designated. Hence, this name is not validly published under Rule 27 of the *Bacteriological Code* (1990 Revision) (Euzéby and Tindall, 2001; Lapage et al., 1992). Nevertheless, because of its wide use, the name is adopted for this volume of the *Manual*. If so designated by the Judicial Commission, the type order is likely to be *Actinomycetales* Buchanan 1917, 162[AL] emend. Zhi, Li and Stackebrandt 2009, 594.

The class *Actinobacteria sensu stricto* encompasses 15 orders, 43 families, and 203 genera. Members of the taxon show a remarkable range of morphologies, these include organisms that form cocci (e.g. *Dermacoccus* and *Micrococcus*), short rods (e.g. *Mycobacterium* and *Tropheryma*), irregular rods (e.g. *Mycetocola*), rods and cocci (e.g. *Arthrobacter* and *Brevibacterium*), and mycelia that fragment into coccoid and rod-like elements (e.g. *Nocardia* and *Oerskovia*). Others show more extensive morphological differentiation ranging from those which produce extensively branched substrate hyphae that bear spores (e.g. *Micromonospora*) or spore vesicles (e.g. *Actinoplanes* and *Dactylosporangium*) to those that form a stable branched mycelium that carries aerial hyphae which differentiate into short or long chains of spores (e.g. *Actinomadura* and *Streptomyces*) or into spore vesicles (e.g. *Planobispora* and *Streptosporanigium*). In general, spores are nonmotile though those released from spore vesicles tend to be motile.

Amongst prokaryotes, members of the class *Actinobacteria*, notably *Streptomyces* strains, are the richest source of natural products, especially clinically useful antibiotics, antimetabolites and antitumor agents (Bérdy, 2005; Newman and Cragg, 2007; Olano et al., 2009). Filamentous actinobacteria account for about 45% of all microbial bioactive secondary metabolites with about 80% of these 7600 compounds being produced by streptomycetes (Bérdy, 2005). Despite this amazing metabolic diversity, it has been estimated that only about 10% of the total number of natural products that can be synthesized by these organisms have been discovered (Watve et al., 2001). *Amycolatopsis*, *Actinoplanes*, *Micromonospora* and strains are also a source of clinically significant antibiotics, whereas members of less well-known genera, such as *Salinispora* and *Verrucosispora*, are showing promise in this respect (Goodfellow and Fiedler, 2010; Jensen, 2010). It seems likely that filamentous actinobacteria belonging to such taxa will remain a source of new chemical entities as the whole-genomes of representatives of such genera contain 20 or more natural-product biosynthetic gene clusters for the production of known or predicted secondary metabolites, as exemplified by *Amycolatopsis mediterranei* strain U32 (Zhao et al., 2010). There is also evidence that actinobacteria isolated from the extremobiosphere will be a rich source of novel natural products (Bull, 2010).

Actinobacteria are widely distributed in aquatic and terrestrial habitats, including extreme habitats, such as deep-sea sediments (Pathom-aree et al., 2006) and hyper-arid desert soils (Okoro et al., 2009). They are particularly common in soil where they have roles in the turnover of organic matter and recalcitrant molecules (Goodfellow and Simpson, 1983; Goodfellow and Williams, 1983). Others are pathogens of animals (e.g. *Actinomadura*, *Mycobacterium*, *Nocardia*, *Propionibacterium*, and *Tropheryma* spp.) and plants (e.g. *Clavibacter*, *Curtobacterium*, *Rhodococcus*, and *Streptomyces* spp.), plant commensals (e.g. *Leifsonia* spp.), nitrogen-forming symbionts (e.g. *Frankia*) and inhabitants of the gastrointestinal tract (*Bifidobacterium* and *Scardovia* spp.). A range of procedures are available for the selective isolation of specific components of actinobacterial communities present in natural habitats (Goodfellow, 2010).

Order I. **Actinomycetales** Buchanan 1917, 162[AL] emend. Zhi, Li and Stackebrandt 2009, 594

Michael Goodfellow

Ac.ti.no.my.ce.ta′les. N.L. masc. n. *Actinomyces* type genus of family, suff. *-ales* ending to denote an order; N.L. pl. fem. n. *Actinomycetales* the *Actinomyces* order.

This taxon is one of 15 orders classified in the class *Actinobacteria*, as recognized in the present volume of the *Manual*. As currently defined the order contains the family *Actinomycetaceae*. Besides the genus *Actinomyces*, the family includes the genera *Actinobaculum*, *Arcanobacterium*, *Mobiluncus*, and *Varibaculum*. The current composition of the order is determined by 16S rRNA gene sequence analysis and by the presence of family-specific patterns of 16S rRNA nucleotide sequences, as cited in the description of the family.

Type genus: **Actinomyces** Harz 1877, 133[AL] emend. Georg, Pine and Gerencser 1969, 292[VP].

Family I. **Actinomycetaceae** Buchanan 1918, 403 (emend. Stackebrandt, Rainey and Ward-Rainey 1997, 484), emend. Zhi, Li and Stackebrandt 2009, 594[VP]

Klaus P. Schaal and Atteyet F. Yassin

Ac.ti.no.my.ce.ta.ce′a.e. N.L. masc. n. *Actinomyces* the type genus of the family; suff. *-aceae* ending to denote the family; N.L. fem. pl. n. *Actinomycetaceae* the *Actinomyces* family.

Most members of the family appear as **Gram-stain-positive, straight or slightly curved, predominantly diphtheroidal, non-motile rods some of which tend to form branched filaments of up to 1 µm in diameter**. **Fragmentation of the filaments readily occurs** producing rod-shaped or coccoid forms. **Several members** of the family are **chiefly or exclusively coccobacillary or coccoid**. However, members of one genus, namely the **genus** *Mobiluncus*, exclusively exhibit **curved, non-branching rods with tapered ends which stain Gram-variable to Gram-negative** although they possess a multilayered Gram-positive cell wall without an outer membrane. Depending on the species, cells are <0.5 µm wide and have a mean length of 1.7 µm or 2.9 µm. They occur singly or in pairs producing a **gull wing appearance** and **are motile by means of multiple flagella**. **None of the *Actinomycetaceae* is acid-fast or forms endospores or conidia**.

Colonies may be filamentous giving a more or less mycelial appearance, but aerial mycelium is usually not formed. Most species produce non-filamentous predominantly white or gray colonies, while some species may develop pigmented colonies (deep red, reddish, brown, pink, pinkish, or yellowish). A few species are β- or α-hemolytic. Most members of the family grow as **facultative anaerobes**, but **some are anaerobic** and **some are able to grow in air.** Carbon dioxide usually stimulates growth. **Catalase may be produced.** Nitrate reduction varies between genera, species, and strains within one species (*Varibaculum cambriense*). **All members of the family are chemo-organotrophs** with comparatively exacting nutritional requirements.

The cell walls of members of the family do not contain diaminopimelic acid. The **amino acid composition of the peptidoglycan** as far as it has been determined **varies between the genera as well as between species of some of the genera** (*Actinobaculum*, *Actinomyces*). The **cellular fatty acid profiles** of the *Actinomycetaceae* comprise **straight-chain saturated** as well as **mono- and diunsaturated fatty acids**, but genera and species differ in the presence or absence of iso- and anteiso-methyl-branched and cyclopropane ring fatty acids. **10-Methyl-branched fatty acids (tuberculostearic acid) and mycolic acids are absent**. Menaquinones are the only respiratory quinones detected so far with menaquinone-9 (MK-9) and/or menaquinone-10 (MK-10) in different structural types occurring at least in three of the five genera of the family. The genera *Actinobaculum*, *Actinomyces*, and *Arcanobacterium* show a phospholipid pattern consisting of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides with or without phosphatidylcholine corresponding to **phospholipid types PI, PII, and PIII**, respectively.

The end products from glucose fermentation include acetic, lactic, and succinic acids with some variation in the amounts of these acids produced by members of different genera. The pattern of 16S rRNA signatures consists of nucleotides at positions 127:234 (R–U), 598:640 (Y–G), 828 (R), 829:857 (G–Y), 952:1229 (C–G), and 986:1219 (A–U) and is identical with that of the suborder *Actinomycineae*. All members of the family occur worldwide as commensals and/or pathogens of man and other animals.

DNA G+C content (mol%): 48–71 (HPLC, T_m).

Type genus: **Actinomyces** Harz 1877, 133[AL], emend. Georg, Pine and Gerencser 1969, 292[VP].

Further descriptive information

The family *Actinomycetaceae* was created by Buchanan in (1918) and originally served as the home of a diverse collection of organisms such as members of the genera *Actinobacillus*, *Actinomyces*, *Leptotrichia*, and *Nocardia*. After several revisions, membership of the family was restricted to bacterial species that appeared to be linked taxonomically by their ability to produce Gram-stain-positive, branching, and subsequently fragmenting filaments without aerial hyphae and spores, by comparatively exacting nutritional requirements, by facultatively anaerobic to anaerobic growth, and by a fermentative type of carbohydrate metabolism (Slack, 1974; Slack and Gerencser, 1975).

Defined on the basis of these common characteristics, the family *Actinomycetaceae* included the genera *Actinomyces*, *Arachnia*, *Bacterionema*, *Bifidobacterium*, and *Rothia* (Slack, 1974). However, the validity of this family concept was increasingly questioned after modern taxonomic techniques such as numerical phenetic, chemotaxonomic, and molecular genetic methods had been applied to the respective organisms (Schaal et al., 2006).

As currently defined, the family *Actinomycetaceae* Buchanan 1918 with the type genus *Actinomyces* Harz 1877, emend. Georg, Pine and Gerencser 1969, is a member of the suborder *Actinomycineae* Stackebrandt, Rainey and Ward-Rainey 1997, emend. Zhi, Li and Stackebrandt 2009, in the order *Actinomycetales* Buchanan 1917 (Approved Lists, 1980), emend. Stackebrandt, Rainey and Ward-Rainey 1997, emend. Zhi, Li and Stackebrandt 2009. Besides the genus *Actinomyces*, the family includes the genera *Actinobaculum* Lawson, Falsen, Åkervall, Vandamme and Collins 1997, *Arcanobacterium* Collins, Jones and Schofield 1983 (effective publication Collins et al., 1982b), emend. Lehnen, Busse, Frölich, Krasinska, Kämpfer and Speck 2006, *Mobiluncus* Spiegel and Roberts 1984b, emend. Hoyles, Collins, Falsen, Nikolaitchouk and McCartney 2004, and *Varibaculum* Hall, Collins, Lawson, Hutson, Falsen, Inganäs and Duerden 2003e.

Actinomyces bovis belonged to one of the first actinomycete species subjected to 16S rRNA gene sequence analysis (Stackebrandt and Woese, 1981). In the meantime, almost complete 16S rRNA gene sequences have been determined for essentially all of the type strains of the species of the family *Actinomycetaceae*. Phylogenetic trees have been included in various publications covering descriptions of novel species and phylogenetic analyses. As the size of databases, selection of members of the family, outgroup organisms, and treeing algorithms differ in these surveys, the respective phylogenetic trees also differ from each other both in the intrafamily structure and in the position of the family within the suborder *Actinomycineae* (Schaal et al., 2006). In this and the following chapter, the interpretation of relatedness at the intrafamily level, as in a previous analysis (Schaal et al., 2006), is again based on the maximum-likelihood (ML) algorithm (Figure 19), included

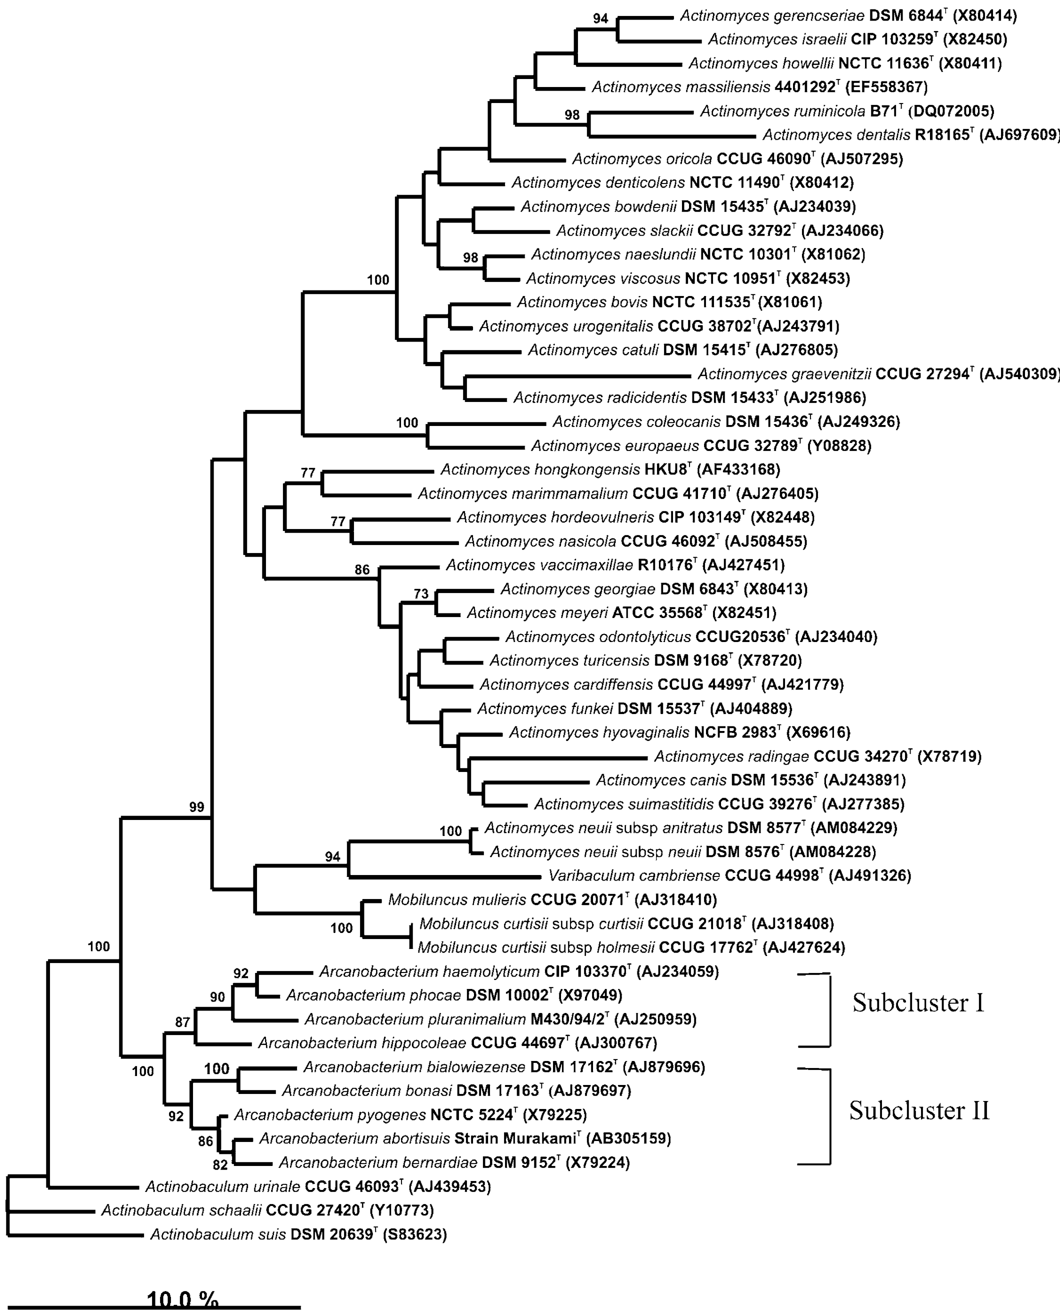

FIGURE 19. Maximum-likelihood tree (Felsenstein, 1993) based on nearly complete 16S rRNA gene sequences showing relationships between representatives of validly described species in the family *Actinomycetaceae*. The numbers at the nodes refer to the level of bootstrap support (%) based upon 500 resamplings. ^{T}, type strain.

in the PHYLIP V version of Felsenstein (1993). Differences in analyses based upon other algorithms such as the neighbor-joining method (Felsenstein, 1993) or the distance matrix algorithm (De Soete, 1983) are rather slight and were discussed earlier (Schaal et al., 2006), but the current ML dendrogram, although including additional species, is in good agreement with that published in 2006.

Based upon both, the phylogenetic position of the type strains of species available in 1997 and on signature nucleotides of the 16S rRNA gene sequences, Stackebrandt et al. (1997) described the suborder *Actinomycineae* for the family *Actinomycetaceae* that branched between the suborders *Micrococcineae* and *Corynebacterineae* (Schaal et al., 2006). The description of these suborders has recently been emended (Zhi et al., 2009). In the description of novel or reclassified *Arcanobacterium* species and a phylogenetic analysis of the genus *Actinomyces* (Pascual Ramos et al., 1997b), the *Actinomycetaceae* branched next to the *Micrococcineae* (only two sequences included) and the *Propionibacterineae*.

Similarity values of 16S rRNA gene sequence analyses for members of the family *Actinomycetaceae* range from 88 to 99%, indicating the presence of several phylogenetically different groups (Figure 19), which are separated by intra-cluster similarity values ranging from 88–90% to 89–92%. As already assumed on the basis of previous numerical phenetic (Schaal and Schofield, 1981a, 1981b, 1984; Schofield and Schaal, 1981) and phylogenetic (Pascual Ramos et al., 1997b) analyses, the genus *Actinomyces* does not represent a monophyletic taxon. Owing to the lack of detailed chemotaxonomic and phenotypic information, the family still serves as a phylogenetic dumping ground. Chemotaxonomic properties, found to correlate well with the phylogenetic structure in other actinobacterial genera, are either not available or not exclusive in phylogenetic clusters. Although tempting, a purely phylogeny-based dissection is not favored as novel sequences may blur the present topology of the family and its genera as is underlined by a comparison between the phylogenetic dendrogram published in 2006 (Schaal et al., 2006) and that presented in Figure 19.

Three clusters in the phylogenetic ML analysis (Figure 19) correspond to the genera *Actinobaculum*, *Arcanobacterium*, and *Mobiluncus*, and *Varibaculum* apparently also deserves genus rank (Collins et al., 1993; Funke et al., 1997a; Hoyles et al., 2001c, 2002b; Nikolaitchouk et al., 2000; Schaal et al., 2006). *Actinobaculum* and *Arcanobacterium* appeared to be phylogenetic neighbors in a previous phylogenetic analysis (Schaal et al., 2006), but may be less related according to the data presented in Figure 19. Furthermore, current 16S rRNA gene sequence data, signature nucleotides and chemotaxonomic characteristics appear to indicate that the genus *Arcanobacterium* is also not monophyletic (see genus *Arcanobacterium*, below).

Mobiluncus and *Varibaculum* species were found to branch adjacent to *Actinomyces neuii* in both the previous and the current analysis. The genera *Actinobaculum*, *Arcanobacterium*, and *Mobiluncus* are all defined by individual signature nucleotides (Table 1). From a phylogenetic point of view, members of the genera *Actinobaculum*, *Arcanobacterium*, *Mobiluncus*, and *Varibaculum* were thought to have originated as descendants of an *Actinomyces* ancestor (Schaal et al., 2006), but even this assumption may change with more sequences included as the present phylogenetic analysis appears to indicate.

Members of the genus *Actinomyces* form several phylogenetic clusters, the number of which depends on the cut-off branching points. As the branching is rarely supported by high bootstrap values, the decision on what level these clusters should be considered taxonomically coherent entities should be based upon results of additional taxonomic investigations such as chemotaxonomic, physiological, and morphological studies. Even within individual clusters, the majority of species are remotely related showing more than 3% dissimilarity between their 16S rRNA gene sequences. Following the suggestion of Stackebrandt and Goebel (1994) that at this low level of relatedness DNA–DNA hybridization would result in values significantly below the species delineation threshold value of around 70% (Wayne et al., 1987), most authors refrained from confirming the species status of the more recently described species by applying this technique to the type strains of the novel species.

Based upon similar cut-off points, *Actinomyces* species (excluding *Actinomyces neuii*) form two major clusters (Figure 19). Cluster 1 contains 15 or 17 (16 or 18 when the novel species *Actinomyces timonensis* is included) species, depending on whether *Actinomyces graevenitzii* and *Actinomyces radicidentis* are included or whether they represent individual lineages. As far as 16S rRNA gene signature nucleotides (Table 1) are concerned, *Actinomyces radicidentis* should be considered a member of cluster 1, whereas *Actinomyces graevenitzii* exhibits deviations from the set of signature nucleotides of core cluster 1 and should thus be treated as a separate phylogenetic unit.

In a previous phylogenetic analysis (Schaal et al., 2006), *Actinomyces coleocanis* and *Actinomyces europaeus* formed a subcluster loosely affiliated with cluster 2. In the current dendrogram (Figure 19), however, these two species appear as a distantly related subgroup of cluster 1 or they form a subgroup similar to that of the two subspecies of *Actinomyces neuii* when the recently described novel species *Actinomyces hominis* is included in the phylogenetic tree (Funke et al., 2010).

All of the remaining *Actinomyces* species except for *Actinomyces neuii* form cluster 2. While the majority of species of cluster 2 (core cluster 2) (Figure 19) is moderately related, two distantly related subclusters of cluster 2 emerge, containing *Actinomyces hongkongensis* and *Actinomyces marimammalium* on the one hand and *Actinomyces hordeovulneris* and *Actinomyces nasicola* on the other hand. In the previous dendrogram (Schaal et al., 2006), *Actinomyces radingae* appeared to form an additional subcluster of cluster 2, while in Figure 19, this species appears to be a member of core cluster 2. This is in good agreement with the signature nucleotides of *Actinomyces radingae* which differ only slightly from those of the members of core cluster 2 (Table 1). The other subclusters mentioned above represent individual lineages that are defined by the signature nucleotides shown in Table 1.

While signature nucleotides or 16S rRNA gene sequences help to differentiate the genera of the family *Actinomycetaceae* from each other, reliable additional differential characteristics are hardly available, especially because detailed morphological, chemotaxonomic, and physiological characterizations remain to be performed for many of the recently described taxa. Nevertheless, Table 2 shows some characteristics that may aid in the differentiation of the genera of the family *Actinomycetaceae*.

Key to the genera of the family *Actinomycetaceae*

I. Cells are Gram-stain-positive, filamentous or rod-shaped and possibly branching, or coccobacillary to coccoid and nonmotile.

1. **DNA G+C content (mol%): 55–71**

Because the genus as currently recognized is obviously polyphyletic, a pattern of 16S rRNA signature nucleotides common to all members of the genus would be of little taxonomic relevance. The signature nucleotides characterizing the phylogenetic clusters and subclusters as shown in Figure 19 are listed in Table 1. Optimal growth occurs at 36±1°C in air with added CO_2 or anaerobically. Only *Actinomyces ruminicola* grows best at 46°C. Members of the genus belong to peptidoglycan types A5α (L-Lys[L-Orn]-L-Lys–D-Glu, two species having L-Lys–L-Lys–D-Glu), A5β (L-Orn–L-Lys–D-Glu), or A4 (L-Lys–D-Asp), respectively (Schleifer and Kandler, 1972; Schleifer and Seidl, 1985). Characteristic cell-wall sugars include galactose, glucose, mannose, rhamnose, and 6-deoxytalose

with characteristic species differences, but not arabinose. Respiratory quinones include different combinations of fully unsaturated menaquinones with eight, nine, and ten isoprene units or the same compounds with varying degrees of saturation and a methyl-substituted menaquinone with ten isoprene units (*methyl*-MK-10) as major components depending on the species involved. The phospholipid patterns belong to phospholipid type I (with no diagnostic phospholipid) and phospholipid type III (with phosphatidylcholine as diagnostic phospholipid) *sensu* Lechevalier et al. (1977). Nearly all species examined so far contain diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids. Straight-chain saturated and monounsaturated fatty acids are generally present as long-chain cellular fatty acids, and some species contain iso-methyl-branched, anteiso-methyl-branched and/or cyclopropane ring fatty acids in addition. Catalase and nitrate reductase may or may not be produced (Table 2).

→ Genus *Actinomyces*

2. **DNA G+C content (mol%): 48–64**

The pattern of 16S rRNA signatures consists of nucleotides at positions 125:236 (U–A), 153:168 (G–U), 316:337 (U–G), 378:385 (A–U), 407:435 (G–C), 419:424 (U–G), 603:635 (U–A), 615:625 (G–Y), 668:738 (U–A), 669:737 (A–U), 722:733 (A.A), and 1308:1329 (U–A) (Table 1). Members of the genus are facultatively anaerobic and usually require an increased CO_2-tension (~5%) for optimal growth at 36±1°C. The cell-wall chemotype is chemotype V (Lechevalier and Lechevalier, 1970) with L-lysine as wall diamino acid and rhamnose as diagnostic whole-cell sugar. The *Arcanobacterium* species examined so far belong to peptidoglycan type A5, but can be assigned to two different subtypes, namely the L-Lys– L-Ala– L-Lys– D-Glu subtype and the L-Lys– L-Lys– D-Glu subtype, corresponding by and large with the 16S rRNA gene sequence similarity-based subdivision of the genus. The muramic acid residue of the glycan moiety of the cell-wall peptidoglycan is *N*-acetylated. The phospholipids identified in members of the genus include diphosphatidylglycerol and phosphatidylglycerol and possibly various additional polar lipids. The principal respiratory quinones are menaquinones with eight, nine, ten, or eleven isoprene units, tetrahydrogenated menaquinones with nine [MK-9(H_4)] or ten [MK-10(H_4)] isoprene units, respectively, being the major components. The cellular fatty acid profile consists predominantly of straight-chain saturated and monounsaturated fatty acids, but iso- and anteiso-branched fatty acids may occur in small amounts. Catalase production is consistently negative in six species (*Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonsai*, *Arcanobacterium hippocoleae*, and *Arcanobacterium pyogenes*) and positive in one species (*Arcanobacterium pluranimalium*). One additional species (*Arcanobacterium phocae*) is catalase-variable and some strains of *Arcanobacterium haemolyticum* may show a weakly positive catalase reaction. The ability to reduce nitrate to nitrite varies between species.

→ Genus *Arcanobacterium*

3. **DNA G+C content (mol%): 55–57**

The pattern of 16S rRNA signatures consists of nucleotides at positions 153:168 (G–U), 316:337 (U–G), 407:435 (G–U), 419:424 (U–G), 603:635 (U–A), 615:625 (G–U), 668:738 (U–A), and 722:733 (A.A) (Table 1). Members of the genus are anaerobic to facultatively anaerobic growing best at 36±1°C. The cell-wall murein types differ between species consisting of either L-Lys– L-Ala– L-Lys– D-Glu or of L-Lys– L-Lys– D-Glu. The cell-wall sugar pattern includes galactose, mannose, and rhamnose (*Actinobaculum suis*). The phospholipid type is PI *sensu* Lechevalier et al. (1977) comprising diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. The respiratory quinones consist of a tetrahydrogenated menaquinone with ten isoprene units [MK-10(H_4)] as the only isoprenoid quinone. The cellular fatty acid profile comprises straight-chain saturated and monounsaturated fatty acids. However, the chemotaxonomic pattern of *Actinobaculum schaalii* appears to differ considerably from that of *Actinobaculum suis*. Catalase- and nitrate reductase-negative.

→ Genus *Actinobaculum*

4. **DNA G+C content (mol%): 52**

Members of the genus are preferentially anaerobic and catalase-negative. The majority of strains reduce nitrate to nitrite. Major end products of glucose fermentation are lactic and succinic acids. Chemotaxonomic properties have not yet been determined. Whole-cell protein profiling using SDS-PAGE demonstrated a considerable phenotypic coherence of members of the single species of the genus and their clear distinctness from *Mobiluncus* species.

→ Genus *Varibaculum*

II. Cells are Gram-stain-variable to Gram-stain-negative, strongly curved rods with tapered ends which occur singly or in pairs producing a gull wing appearance and which are motile by means of multiple, either subpolar or more centrally located flagella.

1. **DNA G+C content (mol%): 49–55**

The pattern of 16S rRNA signatures consists of nucleotides at positions 154:167 (G–U), 378:385 (A–U), 407:435 (G–C), 408:434 (A–U), 441 (U), 450:483 (A–U), 613:627 (A–U), 668:738 (U–A), 722:733 (A.A), 840:846 (G–U), and 1308:1329 (U–A) (Table 1). Despite the variable to negative Gram reaction, members of the genus possess a multilayered Gram-stain-positive cell wall lacking an outer membrane. The whole-cell sugar pattern includes galactose, glucose, and rhamnose. The cellular fatty acid profile consists of straight-chain saturated and mono- and diunsaturated fatty acids with hexadecanoic (16:0), octadecadienoic (18:2), and octadecenoic (18:1) acids being the major components. At least for primary isolation at the optimal growth temperature of 36±1°C, anaerobic growth conditions are required. Addition of serum to the culture medium stimulates growth. Nitrate reduction varies between species or within one species, respectively. Catalase is not produced.

→ Genus *Mobiluncus*

[a]Symbols: +, positive/present; –, negative/absent; +/–, predominantly positive/present; –/+, predominantly negative/absent; (+), weakly or irregularly positive/present; D, differences between species; d, differences between strains within one species; v, variable; nr, not reported.

[b]Data compiled from Holdeman et al. (1977), Schofield and Schaal (1981), Schaal (1986b), and Schaal et al. (2006).

[c]A_2pm, Diaminopimelic acid.

[d]DPG, Diphosphatidylglycerol; PG, phosphatidylglycerol; PC, phosphatidylcholine; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; P type I/P type III, phospholipid types I or III *sensu* Lechevalier et al. (1977).

[e]Menaquinones with 8, 9, 10 or 11 isoprene units and varying degrees of saturation; methyl-MK-10, methyl-substituted menaquinone-10.

[f]S, Straight-chain, saturated; U, unsaturated; A, anteiso-methyl-branched; I, iso-methyl-branched; C, cyclopropane ring fatty acids.

Genus I. **Actinomyces** Harz 1877, 133[AL] emend. Georg, Pine and Gerencser 1969, 292[VP]

Klaus P. Schaal and Atteyet A. Yassin

Ac.ti.no.my′ces. Gr. fem. n. *aktis*, *aktinos* ray; Gr. masc. n. *mukês* fungus; N.L. masc. n. *Actinomyces* ray fungus referring to the radial arrangement of filaments in *Actinomyces bovis* sulfur granules.

Straight or slightly curved rods, 0.2–1.0 µm in diameter, which vary considerably in shape and size, and **slender filaments**, 1 µm or less in width and 10–50 µm or more in length, **with true branching. Short rods** (0.5–5.0 µm in length) **with or without clubbed ends** are frequently seen and **may occur singly, in pairs with diphtheroidal arrangements** (Y, V, T forms and palisades), **in short chains or in small clusters.** Longer (5.0–10.0 µm in length) branched rods are also common. Several members

of the genus appear chiefly or exclusively as **coccobacillary or even coccoid elements**. **Filaments** which may predominate in certain species **are either straight or wavy**, show varying degrees of **branching** and may have **swollen, clubbed, or clavate ends. Gram-stain-positive**, but irregular staining giving rise to a beaded or barred appearance frequently occurs, and two species may be Gram-stain-variable. **Non-acid-fast, nonmotile, and non-endospore-forming.** Conidia are not produced.

Facultatively anaerobic; several species are preferentially anaerobic, some grow well aerobically. **Carbon dioxide is usually required for maximum growth.**

A few species produce characteristic **filamentous microcolonies (spider- or cobweb-like colonies)** after 24–48 h of incubation at 36±1°C which are composed of branched, septate or non-septate filaments with or without signs of central fragmentation. The microcolonies of the remaining species are predominantly or exclusively non-filamentous and consist chiefly of diphtheroidal and/or branched rods, or of coccobacillary or coccoid elements. Several of the recently described new *Actinomyces* species form pinpoint surface colonies after 48 h.

Mature colonies (3–14 d of incubation at 36±1°C depending on the species examined) measure between 0.5 and 5.0 mm in diameter and are **either rough and dry to crumbly in texture or smooth and soft to mucoid, or** they show various degrees of transition between these forms. Most colonies are **white to gray-white** or **creamy white**, but *Actinomyces odontolyticus* develops a **deep red or brown to red pigmentation** when grown on blood agar. The colony pigmentation of a few *Actinomyces* spp. has been described as follows: cream to pinkish (*Actinomyces cardiffensis*), pink (when grown on horse blood agar; *Actinomyces denticolens*), dark brown (*Actinomyces graevenitzii*), brown (*Actinomyces radicidentis*), and reddish (*Actinomyces urogenitalis*). Aerial filaments are usually absent although an occasional rough isolate of *Actinomyces israelii* or *Actinomyces gerencseriae* may produce short aerial threads under certain cultural conditions. **Optimum temperature predominantly 35–37°C** (*Actinomyces meyeri* grows equally well at 30°C and the optimum growth temperature of *Actinomyces ruminicola* **is 46°C**).

Chemo-organotrophic, having a **fermentative type of carbohydrate metabolism.** Carbohydrates are fermented with the production of acid but no gas. **End products from glucose fermentation** include **formic, acetic, lactic, and succinic acids;** the amount of succinic acid formed depends on the concentration of CO_2/HCO_3^- available in the medium or the gaseous environment, respectively. Catalase-negative or -positive; nitrate reduction positive or negative; **indole not produced. Organic nitrogen is required for growth.** Some species may show greening or complete lysis on agar media containing rabbit, sheep, horse, or human red blood cells.

Characteristic **amino acids of the cell-wall peptidoglycan** of those species whose peptidoglycan has been examined in detail are L-lysine and either or neither L-ornithine nor D-β-aspartic acid (peptidoglycan types A4, A5α, and A5β, respectively) ; **diaminopimelic acid (A_2pm) or glycine do not occur.** Cell-wall sugars may include 6-deoxytalose, fucose, galactose, glucose, mannose, and rhamnose, but not arabinose and xylose.

DNA G+C content (mol%): 55–71 (T_m, HPLC).

Type species: **Actinomyces bovis** Harz 1877, 133[AL].

Further descriptive information

Phylogeny. The genus *Actinomyces* is the type genus of the family *Actinomycetaceae* Buchanan (1918) (emend. Stackebrandt et al. 1997, emend. Zhi et al. 2009), within the suborder *Actinomycineae* Stackebrandt et al. 1997, emend. Zhi et al. 2009, of the order *Actinomycetales* Buchanan 1917 (Approved Lists; Skerman et al., 1980) emend. Stackebrandt et al. 1997, emend. Zhi et al. 2009. In addition to *Actinomyces*, the family currently comprises the genera *Arcanobacterium* Collins et al. 1983 (effective publication Collins et al., 1982b), *Actinobaculum* Lawson et al. 1997, *Varibaculum* Hall et al. 2003e, and *Mobiluncus* Spiegel and Roberts 1984b emend. Hoyles et al. 2004. The genera *Actinobaculum* and *Arcanobacterium* both contain species formerly classified in the genus *Actinomyces* (Schaal et al., 2006).

The genus *Actinomyces* apparently does not represent a monophyletic taxon, but forms several phylogenetic clusters (Figure 19) as had already been noted in previous phylogenetic analyses (Lawson et al., 1997; Pascual Ramos et al., 1997b; Schaal et al., 2006) and had even been presumed from the results of numerical taxonomic studies (Schaal and Gatzer, 1985; Schaal and Schofield, 1984; Schofield and Schaal, 1981). As shown in Figure 19, *Actinomyces* species may be separated into two major (core clusters 1 and 2) and four to five additional minor phylogenetic subgroups on the basis of 16S rRNA gene sequence similarity. The taxonomic relevance of this classification scheme will be discussed later.

Cell morphology. The cellular morphology of *Actinomyces* species has traditionally been described as being both diphtheroidal and filamentous (Slack, 1974; Slack and Gerencser, 1975). However, members of different species, as well as individual strains of a single species, may vary considerably with regard to the proportion in which rods and filaments occur. Furthermore, some *Actinomyces* species appear to produce only coccoid or coccobacillary cells. It should also be noted, however, that the cellular appearance may be considerably influenced by factors such as composition of the growth medium, cultural conditions, or age of cultures.

Gram-stained smears or wet mounts prepared from young broth (2–3 d) or agar (3–5 d) cultures, rough mature colonies (7–14 d), or clinical specimens often show groups or clusters of Gram-stain-positive, intertwining filaments, and branching rods which resemble small microcolonies (Figure 20). The staining may be uniform (Figure 20) or irregular (Figure 21), sometimes producing a beaded or barred appearance (Schaal, 1986b; Schaal et al., 2006; Slack and Gerencser, 1975). A granular cytoplasm that might account for the irregular staining properties can also be demonstrated in unstained cells observed in darkfield (Slack and Gerencser, 1975).

The filaments are often wavy, sometimes straight, slender, and of varying length (Figure 20 and Figure 21). Some may have swollen, bulbous ends, and *Actinomyces hordeovulneris* may occasionally form sphaeroplast-like bodies at the tips of the filaments (Buchanan and Scott, 1984). *Actinomyces gerencseriae*, *Actinomyces hordeovulneris*, *Actinomyces israelii*, and fresh isolates of *Actinomyces viscosus sensu stricto* may occur in these branching filamentous structures (Figure 21) and the formation of beaded filaments was also described to be characteristic of *Actinomyces dentalis* (Hall et al., 2005). Filament formation is less common in

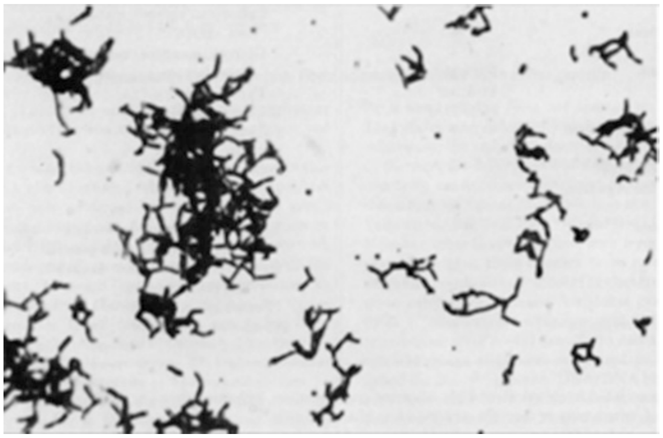

FIGURE 20. *Actinomyces israelii.* Gram-stained smear from a 24-h culture in Tarozzi broth, showing branching filaments, branched rods and diphtheroidal forms; micrograph (1200×).

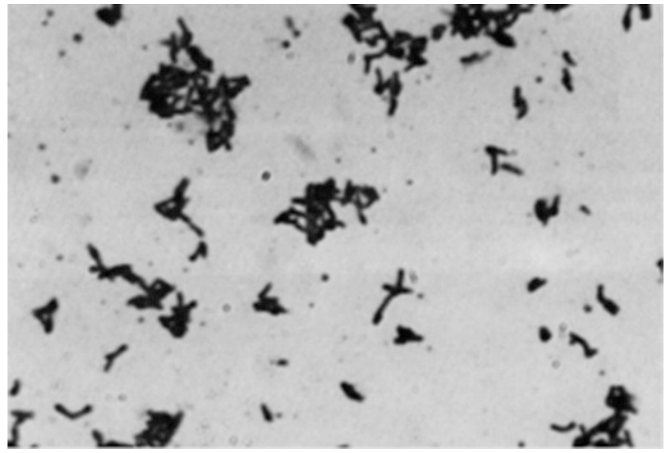

FIGURE 22. *Actinomyces oris* (*Actinomyces viscosus*, serovar II). Gram-stained smear from a 24-h culture in Tarozzi broth, showing irregular rods with some branching and diphtheroidal arrangements; micrograph (1200×).

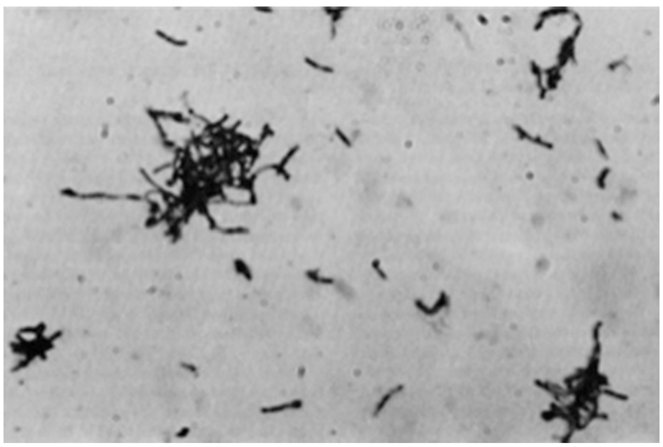

FIGURE 21. *Actinomyces bovis*, serovar II. Gram-stained smear from a 24-h culture in Tarozzi broth, showing wavy, irregularly stained filaments as well as branched and diphtheroidal rods; micrograph (1200×).

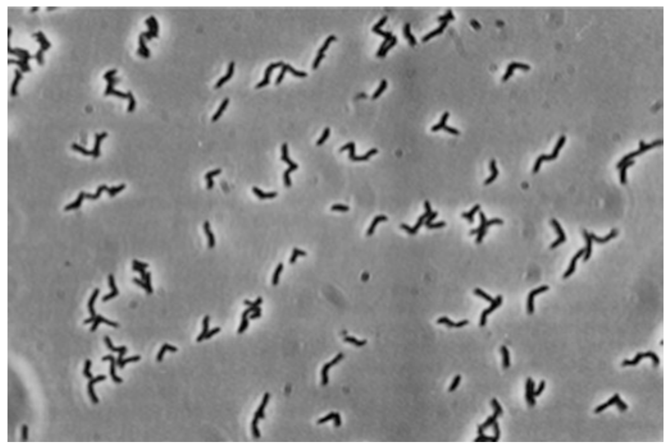

FIGURE 23. *Actinomyces naeslundii.* Wet mount in lactophenol cotton blue mounting fluid prepared from a mature colony, showing curved and branched rods in diphtheroidal arrangements (BHIA, 14 d, 36°C); phase-contrast micrograph (1200×).

Actinomyces johnsonii, *Actinomyces naeslundii*, *Actinomyces oris*, laboratory strains of *Actinomyces denticolens*, *Actinomyces oricola*, and *Actinomyces viscosus* (Hall et al., 2003c), rare in *Actinomyces bovis*, *Actinomyces howellii*, and *Actinomyces odontolyticus*, and very rare in *Actinomyces meyeri* although very young cultures or an occasional rough strain of the latter four species (Figure 21) may be definitely filamentous. All of the other *Actinomyces* species have not been reported as being predominantly filamentous or have not been characterized morphologically in sufficient detail.

The cellular morphology of many *Actinomyces* cultures is predominantly or completely diphtheroidal, and even pus specimens derived from *Actinomyces* infections may only contain short or medium-sized rods with or without branching unless one of the coccoid species is present. *Actinomyces viscosus* serovar II strains (Figure 22), which were assigned to *Actinomyces naeslundii* genospecies 2 and were recently classified as *Actinomyces oris*, smooth *Actinomyces naeslundii sensu stricto* (Figure 23) and *Actinomyces viscosus sensu stricto* strains, *Actinomyces bowdenii* (Pascual et al., 1999), *Actinomyces canis* (Hoyles et al., 2000), *Actinomyces cardiffensis* (Hall et al., 2002), *Actinomyces catuli* (Hoyles et al., 2001b), *Actinomyces coleocanis* (Hoyles et al., 2001c), *Actinomyces funkei* (Lawson et al., 2001b), *Actinomyces georgiae* (Johnson et al., 1990), *Actinomyces graevenitzii* (Pascual Ramos et al., 1997a), *Actinomyces howellii*, *Actinomyces johnsonii*, *Actinomyces marimammalium* (Hoyles et al., 2001c), *Actinomyces suimastitidis* (Hoyles et al., 2001a), *Actinomyces turicensis* (Vandamme et al., 1998; Wüst et al., 1995a), *Actinomyces urogenitalis* (Nikolaitchouk et al., 2000), and some *Actinomyces gerencseriae* isolates produce comparatively long to medium-sized, straight to slightly curved rods which often show branching and/or characteristic arrangements in Y, V, and T forms. However, Gram-stained smears of *Actinomyces cardiffensis* may also contain beaded branching filaments. *Actinomyces hongkongensis* (Woo et al., 2003), *Actinomyces massiliensis* (Renvoise et al., 2009), and *Actinomyces ruminicola* (An et al., 2006) are characterized by straight, short to medium-sized rods. Shorter irregular rods resembling propionibacteria are frequently seen in *Actinomyces bovis* (Figure 24), *Actinomyces*

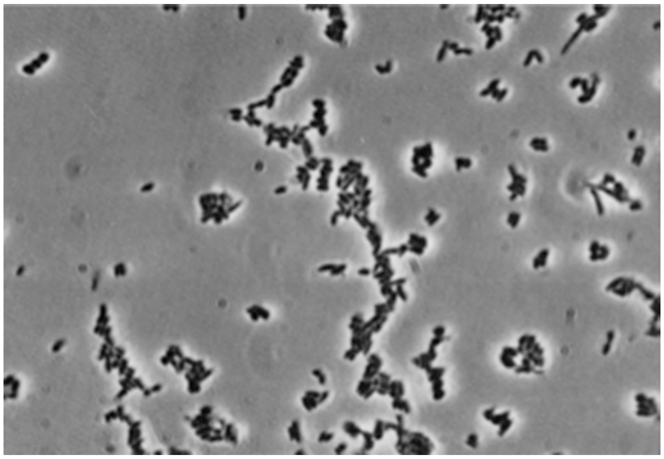

FIGURE 24. *Actinomyces bovis*, serovar I. Wet mount in lactophenol cotton blue mounting fluid prepared from a mature colony, showing short and a few longer rods (BHIA, 14 d, 36°C); phase-contrast micrograph (1200×).

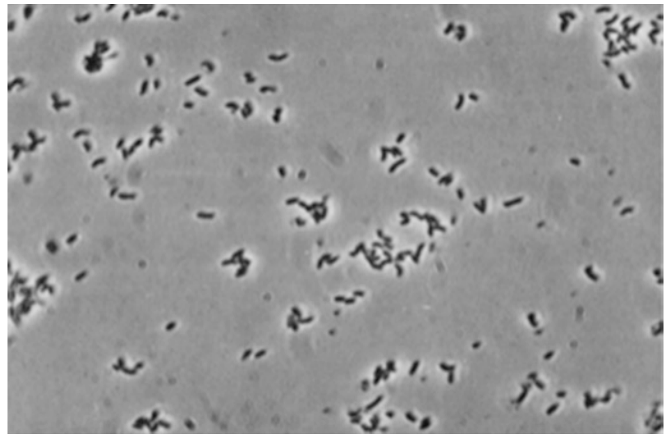

FIGURE 26. *Actinomyces odontolyticus*, serovar I. Wet mount in lactophenol cotton blue mounting fluid prepared from a mature colony, showing short diphtheroidal rods (BHIA, 14 d, 36°C); phase-contrast micrograph (1200×).

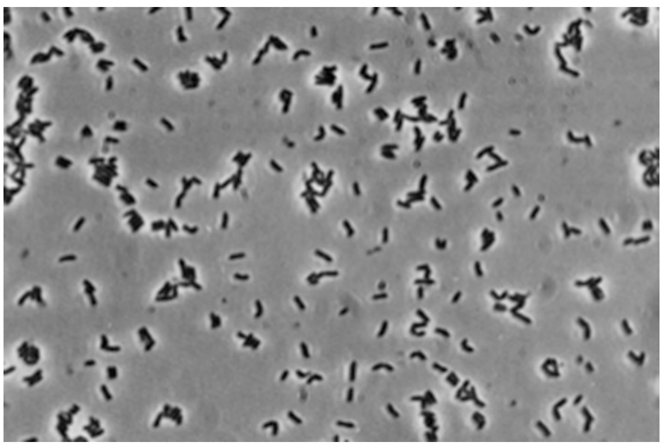

FIGURE 25. *Actinomyces denticolens*. Wet mount in lactophenol cotton blue mounting fluid prepared from a mature colony, showing predominantly diphtheroidal rods (BHIA, 10 d, 36°C); phase-contrast micrograph (1200×).

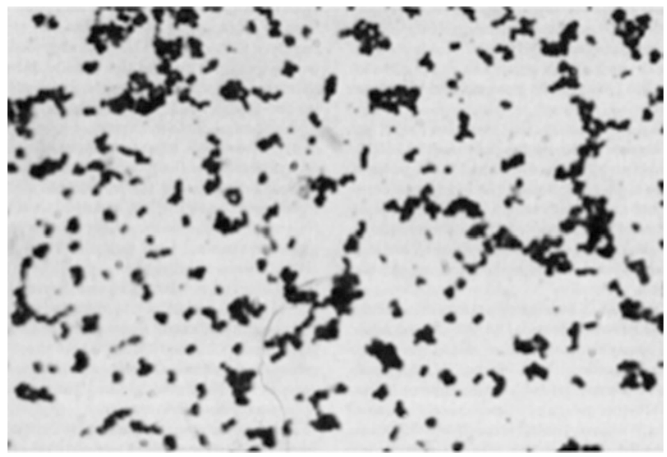

FIGURE 27. *Actinomyces odontolyticus*, serovar II. Gram-stained smear from a 48-h culture in Tarozzi broth, showing coccobacillary and coccoid elements; micrograph (1200×).

denticolens (Dent and Williams, 1984b) (Figure 25), *Actinomyces meyeri* (Cato et al., 1984), and *Actinomyces odontolyticus* (Figure 26) cultures, and may be arranged in palisades as well as in other diphtheroidal arrangements. *Actinomyces hyovaginalis* (Collins et al., 1993), *Actinomyces nasicola* (Hall et al., 2003d), and *Actinomyces neuii* (Funke et al., 1994) usually appear as short, diphtheroidal rods, but some branching and/or coccoid or coccobacillary forms may occur. Coccobacillary or coccoid elements are uncommon in the "classical" *Actinomyces* species although they may predominate in certain *Actinomyces bovis* and *Actinomyces odontolyticus* cultures (Figure 27), and they are also found in *Actinomyces vaccimaxillae* (Hall et al., 2003a) together with short diphtheroidal rods. *Actinomyces europaeus* (Funke et al., 1997a), *Actinomyces radicidentis* (Collins et al., 2000), *Actinomyces radingae* (Vandamme et al., 1998), and *Actinomyces slackii* (Dent and Williams, 1986) characteristically form only coccoid or coccobacillary elements.

Cell-wall composition. The species currently included in the genus *Actinomyces* display considerable chemotaxonomic heterogeneity in particular with regard to their amino acid composition of the cell-wall peptidoglycan, DNA base ratio values, cell-wall sugars, as well as their menaquinone, polar lipid, and cellular fatty acid composition.

In most of the members of the genus *Actinomyces*, the muramic acid residue of the glycan moiety of the cell-wall peptidoglycan is *N*-acetylated; up to the present, only *Actinomyces hordeovulneris* was found to possess the *N*-glycolated form of this cell-wall constituent (Schaal, 1999), at least as far as the acyl types of *Actinomyces* species have already been determined. The mode of cross-linkage and the amino acid composition of the tetrapeptide bridge of the peptidoglycan layer of members of the genus *Actinomyces* is complex. Using the methods of Schleifer and Kandler (1972), modified by the application of cellulose sheets (Merck, Darmstadt, Germany) for ascending thin-layer chromatography (Weiss, unpublished), the cross-linking between the

amino group of the diamino acid in position 3 of the peptide side chain and the carboxyl group of D-alanine in position 4 of the adjacent tetrapeptide varies between *Actinomyces* species.

The peptidoglycan of *Actinomyces bovis*, the type species of the genus, was characterized by Schleifer and Kandler (1972) as containing a typical L-alanine, D-glutamic acid, L-lysine, D-alanine sequence in the peptide moiety and a D-aspartic acid cross-link between L-lysine in position 3 of one tetrapeptide unit and D-alanine of the corresponding subunit (L-Lys–D-Asp). This peptidoglycan type was abbreviated as peptidoglycan type A4. However, the findings of Schleifer and Seidl (1985) appear to indicate that the *Actinomyces bovis* peptidoglycan is of the L-Lys–L-Lys–D-Asp type with L-lysine in position 3 of the tetrapeptide and L-lysine and D-aspartic acid in the interpeptide bridge. As both variations of the peptidoglycan contain D-aspartic acid, those filamentous strains of *Actinomyces bovis* that were reported to lack aspartic acid (Pine and Boone, 1967) would thus belong to a different murein type, a finding which still awaits further elucidation.

All of the remaining *Actinomyces* species studied so far belong to peptidoglycan type A5 (Schleifer and Seidl, 1985), which is characterized by the presence of a diamino acid in the interpeptide bridge. This type is common, though not exclusive, among *Actinomycetaceae* strains and appears to be restricted to this group of bacteria. Type A5 occurs in several variations designated A5α, A5β, etc. *Actinomyces europaeus* and *Actinomyces neuii* were found to belong to subtype A5α (L-Lys–L-Lys–D-Glu) (Funke et al., 1997a). *Actinomyces radingae* also shows this subtype with L-lysine in position 3 of the tetrapeptide subunit being partially replaced by L-ornithine (L-Lys[L-Orn]-L-Lys–D-Glu) (Wüst et al., 1995a). *Actinomyces turicensis* is characterized by peptidoglycan subtype A5β with L-ornithine as the diamino acid in position 3 of the tetrapeptide (L-Orn–L-Lys–D-Glu) which is identical to that of *Actinomyces israelii* (Schleifer and Seidl, 1985; Wüst et al., 1995a).

The detailed structures of the peptidoglycan of *Actinomyces* species as far as they have been determined do not support the taxonomic homogeneity of the genus and are therefore in at least partial agreement with the findings derived from 16S rRNA gene sequencing (Schaal et al., 2006). For example, *Actinomyces georgiae*, *Actinomyces gerencseriae*, *Actinomyces hyovaginalis*, *Actinomyces israelii*, and *Actinomyces turicensis* all exhibit the type A5β (L-Orn–L-Lys–D-Glu), *Actinomyces radingae* has type A5α with L-Lys(L-Orn)-L-Lys–D-Glu, and *Actinomyces europaeus* and *Actinomyces neuii* have the type A5α with L-Lys–Lys–D-Glu.

Apart from *Actinomyces bovis*, *Actinomyces europaeus*, and *Actinomyces neuii*, all of the other species of the genus *Actinomyces* studied so far contain L-ornithine in their cell-wall peptidoglycan and have therefore definitely or presumably the peptidoglycan type A5β. With the exception of *Actinomyces radingae*, which was assigned to A5α, these are *Actinomyces denticolens*, *Actinomyces gerencseriae*, *Actinomyces hordeovulneris*, *Actinomyces howellii*, *Actinomyces hyovaginalis*, *Actinomyces israelii*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, and *Actinomyces slackii*, as well as presumably *Actinomyces johnsonii*, *Actinomyces oris*, and *Actinomyces viscosus* (Buchanan et al., 1984; Collins et al., 1993; Dent and Williams, 1984b, 1984c, 1986; Schleifer and Kandler, 1972).

The cell-wall sugars of *Actinomyces* species may include 6-deoxytalose, fucose, galactose, glucose, mannose, and rhamnose which may be present singly or in various combinations (Buchanan et al., 1984; Dent and Williams, 1984b, 1986; Pine, 1963; Schaal, 1999; Slack, 1974; Slack and Gerencser, 1975). *Actinomyces gerencseriae* and *Actinomyces israelii* contain only one detectable sugar, galactose, in their walls (Cummins and Harris, 1958; Schaal et al., 2006). Galactose is also the only or principal sugar component of the walls of both subspecies of *Actinomyces neuii* and of *Actinomyces georgiae* and *Actinomyces radingae* (Schaal, 1999). In contrast, rhamnose was the sole cell-wall sugar detected in *Actinomyces denticolens* (Dent and Williams, 1984b).

All of the other *Actinomyces* species investigated so far exhibit more complex sugar patterns: In *Actinomyces bovis* cell walls, 6-deoxytalose and rhamnose were identified together with smaller amounts of glucose and mannose (Cummins and Harris, 1958, 1959; Schaal, 1999; Slack, 1974; Slack and Gerencser, 1975). Whether fucose is usually present remains to be clarified (Schaal et al., 2006). According to the previous definition of the species, *Actinomyces naeslundii* walls were reported to contain 6-deoxytalose, glucose, mannose, rhamnose, and occasionally fucose (Boone and Pine, 1968; Cummins and Harris, 1958; Hammond et al., 1973; Slack, 1974; Slack and Gerencser, 1975). However, a re-evaluation of these data (Dent and Williams, 1984b) showed that certain of these *Actinomyces naeslundii* strains lack 6-deoxytalose, and mannose was not detected at all. It remains to be seen whether these differences correlate with the subdivision of the species into *Actinomyces naeslundii sensu stricto*, *Actinomyces oris*, and *Actinomyces johnsonii*. The sugar pattern of *Actinomyces viscosus* as previously defined is similar to that of *Actinomyces naeslundii sensu lato* in that it encompasses 6-deoxytalose, glucose, and rhamnose as characteristic components (Dent and Williams, 1984b; Schaal, 1999; Slack, 1974; Slack and Gerencser, 1975). However, some strains may have varying amounts of galactose and small amounts of mannose in addition to the above components (Dent and Williams, 1984b; Schaal, 1999; Slack, 1974) while isolates from dogs may lack 6-deoxytalose (Buchanan et al., 1984). Results on the sugar pattern of *Actinomyces odontolyticus* have remained contradictory: Hammond et al. (1973) and Slack and Gerencser (1975) claimed that galactose, glucose, and mannose, but no 6-deoxytalose or rhamnose were present in walls of this species. On the other hand, Slack (1974), in his contribution to the 8th edition of *Bergey's Manual of Determinative Bacteriology*, listed 6-deoxytalose, fucose, galactose, glucose, mannose, and rhamnose as sugar components characteristic of *Actinomyces odontolyticus*. The findings of Dent and Williams (1984b) who analyzed two strains of *Actinomyces odontolyticus* (NCTC 9931, NCTC 9935) and of Schaal et al. (1999) are similar to those reported by Slack in (1974) and support the view that at least certain strains of this species may have a sugar pattern that includes 6-deoxytalose, glucose, mannose, and rhamnose as principal components. *Actinomyces howellii* cell-wall carbohydrates were reported to comprise glucose and rhamnose, but not 6-deoxytalose (Dent and Williams, 1984c). However, Schaal et al. (1999) also identified galactose and mannose in addition to the above two sugars in this organism. The walls of *Actinomyces hordeovulneris* contain galactose and glucose, while 6-deoxytalose and rhamnose are absent (Buchanan et al., 1984; Schaal, 1999). The sugar pattern of *Actinomyces slackii* is composed of glucose and rhamnose, and may also include galactose (Dent and Williams, 1986; Schaal, 1999). *Actinomyces*

hyovaginalis, *Actinomyces meyeri*, and *Actinomyces turicensis* all contain fucose in their walls (Schaal, 1999). In addition, *Actinomyces turicensis* walls were reported to contain 6-deoxytalose and rhamnose (Schaal, 1999). Besides fucose, the sugar pattern of *Actinomyces hyovaginalis* comprises galactose, glucose, and rhamnose (Schaal, 1999). The sugar content of *Actinomyces meyeri* is most complex as it includes galactose, glucose, mannose, and rhamnose in addition to fucose (Schaal, 1999).

Other chemotaxonomic characteristics. Early reports (Amdur et al., 1978; Kroppenstedt and Kutzner, 1976, 1978; Schaal, 1986b) appeared to indicate that the cellular fatty acid profiles of members of the genus *Actinomyces* were rather simple, encompassing predominantly even numbered, *n*-saturated and *n*-unsaturated, but no branched-chain, odd-numbered, or hydroxyl substituted fatty acids. Thus, whole-organism extracts of *Actinomyces bovis*, *Actinomyces israelii*, *Actinomyces naeslundii*, and *Actinomyces viscosus* as previously defined, as well as *Actinomyces odontolyticus* were reported to contain tetradecanoic ($C_{14:0}$, myristic acid), hexadecanoic ($C_{16:0}$, palmitic acid), octadecanoic ($C_{18:0}$, stearic acid) and octadecenoic ($C_{18:1}$ ω9*c*, oleic acid) acids, possibly together with small amounts of dodecanoic ($C_{12:0}$, *Actinomyces naeslundii sensu lato*) and C_{20} acids (Amdur et al., 1978; Kroppenstedt and Kutzner, 1978). *Actinomyces bovis* may contain larger amounts of octadecanoic acid (Amdur et al., 1978) while these acids constitute only a small part of the fatty acid profiles of the remaining species mentioned before.

In the description of the two genospecies of *Actinomyces naeslundii* and of *Actinomyces* serovar WVA 963 (Johnson et al., 1990), a detailed analysis of their fatty acid profiles was included. According to this analysis, *Actinomyces naeslundii* genospecies 1 which represents *Actinomyces naeslundii sensu stricto* (Henssge et al., 2009), contains $C_{16:0}$, $C_{18:1}$ ω9*c*, and $C_{18:0}$ as major fatty acids together with small amounts of $C_{10:0}$, $C_{12:0}$, $C_{14:0}$, $C_{16:1}$ ω7 *c*, and $C_{16:1}$ ω9*c*. The profile of *Actinomyces naeslundii* genospecies 2, which has recently been described formally as *Actinomyces oris*, is very similar to that of *Actinomyces naeslundii sensu stricto*. The same is true for the profile of *Actinomyces* serovar WVA 963 which has recently been described as *Actinomyces johnsonii* (Henssge et al., 2009). The fatty acid composition of *Actinomyces viscosus* serovar I, which now represents *Actinomyces viscosus sensu stricto*, differs from that of the other species from the *Actinomyces naeslundii/Actinomyces viscosus* complex both qualitatively and quantitatively: According to its new definition, *Actinomyces viscosus* contains small amounts of $C_{18:2}$ ω9,12*c* fatty acids which have been identified neither in *Actinomyces naeslundii sensu stricto* nor in *Actinomyces oris* or *Actinomyces johnsonii*. Furthermore, the relative amount of $C_{16:0}$ present is comparatively low while the content of $C_{10:0}$ is comparatively high.

Other studies on the fatty acid composition of *Actinomyces* species showed that methyl branched-chain fatty acids of the iso and anteiso type, as well as fatty acids which contain a cyclopropane ring, are also not uncommon (Schaal, 1999). The occurrence of cyclopropane fatty acids in a strain of *Actinomyces israelii* (DSM 43305) had already been claimed by Kroppenstedt and Kutzner (1978), but could not be confirmed by Amdur et al. (1978). In the comparative taxonomic study of Schaal et al. (1999), *Actinomyces denticolens*, *Actinomyces gerencseriae*, *Actinomyces hordeovulneris*, *Actinomyces slackii*, and *Actinomyces viscosus* serovar II (*Actinomyces oris*) were found to contain branched-chain fatty acids of the iso and anteiso type. In the same study, saturated and unsaturated fatty acids were detected in all of the *Actinomyces* species examined (*Actinomyces denticolens*, *Actinomyces gerencseriae*, *Actinomyces howellii*, *Actinomyces meyeri*, *Actinomyces slackii*, and *Actinomyces viscosus* serovar II), apart from *Actinomyces hordeovulneris* which only contained saturated fatty acids in addition to the branched-chain ones.

The fatty acid profiles of the two subspecies of *Actinomyces neuii*, as well as those of *Actinomyces europaeus*, *Actinomyces oricola*, and *Actinomyces ruminicola* comprise palmitic ($C_{16:0}$), stearic ($C_{18:0}$), and oleic ($C_{18:1}$ ω9*c*) acids as predominant components (An et al., 2006; Funke et al., 1997a; Funke et al., 1994; Hall et al., 2003c). In addition to these acids, whole-cell extracts of *Actinomyces massiliensis* were found to contain a mixture of $C_{18:2}$ ω6,9*c* and C_{18} anteiso, as well as $C_{12:0}$, $C_{14:0}$, $C_{16:1}$ ω9*c*, and $C_{16:1}$ ω7*c* (Renvoise et al., 2009). The spectrum of cellular fatty acids identified in *Actinomyces radingae* and *Actinomyces turicensis* consisted of $C_{10:0}$, $C_{14:0}$, $C_{16:1}$ ω9*c*, $C_{16:0}$, and $C_{18:1}$ ω9*c*, and another $C_{18:1}$ fatty acid in addition (Wüst et al., 1995a). *Actinomyces graevenitzii* cells were reported to contain $C_{12:0}$, $C_{14:0}$, $C_{16:1}$ ω9, $C_{16:0}$, $C_{18:1}$ ω9, and $C_{18:0}$ fatty acids (Pascual Ramos et al., 1997a). In *Actinomyces nasicola*, $C_{15:0}$ anteiso, $C_{16:0}$, $C_{18:0}$, and $C_{18:1}$ ω9*c* were identified as the major fatty acids (Hall et al., 2003d).

Yribarren and Vilkas (1974) and Pandhi and Hammond (1978) were the first to determine polar lipids in four *Actinomyces viscosus sensu lato* strains: The total lipid content of this species ranged from 3.5 to 5.5% of dry weight. Pandhi and Hammond (1978) identified the polar lipids as cardiolipin, galactosyldiglyceride, phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol dimannosides. Phosphatidylethanolamine and phosphatidylinositol were not detected. This is in contrast to the findings of Yribarren and Vilkas (1974) who reported that their *Actinomyces viscosus sensu lato* strains contained phosphatidylethanolamine.

In a comparative chemotaxonomic study of *Actinomyces* species (Schaal, 1999), two different phospholipid types were identified, namely phospholipid type I (PI) (with no diagnostic phospholipid) and phospholipids type III (PIII) (with phosphatidylcholine as diagnostic lipid) *sensu* Lechevalier et al. (1977). *Actinomyces bovis* (DPG, PC, PI?, PIM?), *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces meyeri* (DPG, PC, PI), *Actinomyces naeslundii sensu lato*, *Actinomyces neuii*, and *Actinomyces viscosus sensu lato* were assigned to phospholipid type III (DPG, PG, PC, PI, and PIM*). Phospholipid type I (DPG, PG, PI, and PIM) was found to be characteristic of *Actinomyces denticolens*, *Actinomyces hordeovulneris*, and *Actinomyces howellii*.

The principal respiratory quinones found in *Actinomyces* species are menaquinones with eight, nine, ten, and eleven isoprene units. *Actinomyces bovis*, *Actinomyces canis*, *Actinomyces graevenitzii*, *Actinomyces hordeovulneris*, *Actinomyces nasicola*, and *Actinomyces ruminicola* thus far appear to be the only members of the genus which contain fully saturated menaquinones, whereas the remaining species possess menaquinones with varying degrees of saturation (Schaal et al., 2006). In *Actinomyces bovis* and *Actinomyces ruminicola*, menaquinones with nine and ten isoprene units (MK-9, MK-10) were identified (An et al., 2006; Schaal, 1999); *Actinomyces bovis* was found to contain *methyl-*

*DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PC, phosphatidylcholine; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides.

MK-10 in addition (Schaal, 1999). *Actinomyces hordeovulneris* contains MK-8 and MK-9 (Schaal, 1999) and the major menaquinone of *Actinomyces nasicola* is MK-9 (Hall et al., 2003d). The major menaquinone of *Actinomyces bowdenii* (Pascual et al., 1999), *Actinomyces gerencseriae*, *Actinomyces howellii*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, *Actinomyces slackii* (Schaal, 1999), and *Actinomyces viscosus* serovar II (*Actinomyces oris*), is MK-10(H_4) although at least *Actinomyces naeslundii sensu lato*, *Actinomyces slackii*, and *Actinomyces viscosus* serovar II (*Actinomyces oris*) may also contain substantial amounts of MK-9(H_4). The two subspecies of *Actinomyces neuii* are characterized by MK-8(H_4) and MK-9(H_4) (Schaal, 1999). In preparations of *Actinomyces meyeri*, MK-9(H_4), MK-10(H_4), MK-11(H_4), and *methyl*-MK-12(H_4) were identified (Schaal, 1999). Only for *Actinomyces coleocanis*, the complete absence of respiratory menaquinones was reported (Hoyles et al., 2002a), a result which awaits confirmation.

The chemotaxonomic data as outlined above underpin the heterogeneity of the genus *Actinomyces* as demonstrated by 16S rRNA gene sequencing although the chemotaxonomic patterns obtained so far are not in full agreement with the different subclusters that can be discerned in phylogenetic dendrograms.

Fine structure. The cell morphology of *Actinomyces* species as observed by electron microscopy of ultrathin sections reflects the picture obtained by light microscopy: cells of most species present as bacillary structures of varying length with or without clubbed ends. In the "classical" *Actinomyces* species, branching can readily be demonstrated (Duda and Slack, 1972; Lai and Listgarten, 1980; Overman and Pine, 1963; Slack and Gerencser, 1975). It should be noted, however, that detailed electron microscopy studies of the recently described newer species have not been performed.

Septum formation can easily be seen in most of the ultrathin sections analyzed so far (Duda and Slack, 1972; Slack and Gerencser, 1975). The septa are not always at a right angle to the longitudinal axis of the cell and the completed cross-walls are often curved (Duda and Slack, 1972). Cells divided by cross-wall formation do not necessarily separate, so that a straight row of rods may result (Duda and Slack, 1972).

Cross-walls dividing rod-shaped elements into two approximately equal parts were taken as an indication for the occurrence of binary fission (Slack and Gerencser, 1975). However, bacteria which typically multiply by binary fission synthesize new cell-wall material either along the whole length of the cell body or in the center part of the rod leading to conservation of the apices (Locci and Schaal, 1980). In contrast, the *Actinomyces* species investigated so far exclusively showed apical growth at one or both ends of the rod-shaped propagule. As evidenced by scanning electron microscopy (Locci, 1978) and immunofluorescence labeling (Locci and Schaal, 1980), new cell-wall material is only formed at the tips of the cell while the interpolar part of the envelope remains unchanged. The unipolar or bipolar extension of the rods resulting from the apical synthesis of new wall material leads to elongated cells or filaments which divide by septum formation and may separate into rod-shaped elements by fragmentation (Locci, 1976; Locci and Schaal, 1980).

The mode of cell growth and division outlined above may be described more appropriately by the term "budding" than by "binary fission". Budding is obviously also responsible for the formation of side branches (Locci and Schaal, 1980). In this respect, electron microscopy of ultrathin sections provided essentially the same information (Slack and Gerencser, 1975). Whether the recently described coccoid or coccobacillary *Actinomyces* species follow the same way of synthesizing new cell-wall material remains to be demonstrated.

The Gram-stain-positive cell walls of *Actinomyces* species have a bilayered structure (Duda and Slack, 1972; Lai and Listgarten, 1980). They consist of a moderately electron-dense outer layer and a thinner, more electron-dense, inner layer. The thickness of the inner layer is 3.6–9.0 nm depending on the species examined. In *Actinomyces bovis*, this inner layer of the cell wall was not detectable (Lai and Listgarten, 1980). Measurements of the thickness of the outer layer indicated pronounced interspecies variation ranging from 14 nm in *Actinomyces bovis* to 36 nm in *Actinomyces israelii* (Lai and Listgarten, 1980). Analogous differences were observed for the overall width of the walls of various *Actinomyces* species although the absolute figures given by different investigators vary considerably. In the following compilation, wall thickness data are listed in this order: Overman and Pine (1963), Duda and Slack (1972), and Lai and Listgarten (1980). According to these authors, the wall thickness was found to be as follows: *Actinomyces bovis*, 10:31:14–22 nm; *Actinomyces israelii*, 29:65:35–50 nm; *Actinomyces naeslundii sensu lato*, 20:45:25–35 nm; *Actinomyces odontolyticus*, not determined (nd):31:22–27 nm; *Actinomyces viscosus sensu lato*, (nd):35:23–28 nm.

In most of the *Actinomyces* strains investigated so far, the external contour of the outer cell-wall layer was described as fuzzy or shaggy (Duda and Slack, 1972; Lai and Listgarten, 1980). *Actinomyces bovis*, *Actinomyces naeslundii sensu lato*, and certain strains of *Actinomyces israelii* and *Actinomyces viscosus sensu lato* may produce long filamentous projections radiating from the cell-wall surface (Lai and Listgarten, 1980; Slack and Gerencser, 1975). Using negatively stained preparations, electron microscopy revealed the presence of hair-like fimbriae protruding through a thick surface coat on some strains of *Actinomyces israelii* (Figdor and Davies, 1997). These surface fibrils or fimbriae obviously play an important role in the attachment of these microbes to epithelial cells, tooth surfaces, or other bacteria (Ellen et al., 1978; Figdor and Davies, 1997; Girard and Jacius, 1974; McIntire et al., 1978). The detection of the "surface fuzz" is markedly influenced by the culture conditions used, with broth-grown cells usually exhibiting longer appendages than blood agar-grown organisms (Lai and Listgarten, 1980). Nevertheless, *Actinomyces odontolyticus* and some strains of *Actinomyces israelii* and *Actinomyces viscosus sensu lato* were reported to produce neither long nor short surface fibrils (Lai and Listgarten, 1980).

Actinomyces odontolyticus cells show a marked increase in electron-density at the cell-wall surface. This increase can also be demonstrated, although to a lesser extent, in *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato*, but is apparently absent in *Actinomyces bovis* (Lai and Listgarten, 1980).

The cytoplasmic membrane of *Actinomyces* species has the usual trilaminar structure (Lai and Listgarten, 1980), but is not always readily discernible (Slack and Gerencser, 1975). A nucleoid without a membrane could be visualized in most species (Duda and Slack, 1972; Lai and Listgarten, 1980). The occurrence of mesosomes has been described for all species examined so far (Duda and Slack, 1972; Lai and Listgarten, 1980; Overman

and Pine, 1963). However, they vary widely in number, size, and type. Simple tubular structures were observed most frequently, but coiled forms were also seen (Slack and Gerencser, 1975). Most of these membranous figures appeared to be derived from the cytoplasmic membrane with which they were often found to be in continuity (Lai and Listgarten, 1980; Overman and Pine, 1963). The cytoplasm of actively growing cells may be densely packed with ribosomes, and electron-dense cytoplasmic inclusions were observed in most species (Duda and Slack, 1972; Lai and Listgarten, 1980).

Cultural characteristics. The morphology of *Actinomyces* microcolonies, although previously thought to be indicative of the genus, may vary considerably, depending on both species affiliation of the strain under study and the media and incubation conditions employed. Nevertheless, standardization of the latter factors usually results in morphological features of the colonies which are fairly reproducible and comparatively diagnostic of some of the various species (Schaal and Pulverer, 1981; Schaal et al., 2006; Slack and Gerencser, 1975). However, most of the recently published *Actinomyces* species are rather fast-growing so that their colonies are macroscopically visible after 24 or 48 h when the traditional species of the genus usually only appear as microcolonies (e.g. An et al., 2006; Hall et al., 2003a, 2003c, 2003d, 2005; Lawson et al., 2001b; Renvoise et al., 2009; Woo et al., 2003).

Microcolonies are observed most appropriately on transparent agar media [brain heart infusion agar (BHIA) or CC-medium*] incubated anaerobically or in air with added CO_2 for 18–48 h and viewed *in situ* under the microscope in transmitted light (Erikson, 1940; Lentze, 1938b) or using the slide culture technique (Schaal, 1986b; Schaal et al., 2006).

Using these culture conditions and observation techniques, several characteristic types of *Actinomyces* microcolonies can be discerned. *Actinomyces gerencseriae*, *Actinomyces hordeovulneris*, and *Actinomyces israelii*, produce microcolonies which are regularly filamentous (Buchanan et al., 1984; Schaal, 1986b; Schaal et al., 2006; Slack and Gerencser, 1975), but may vary in the number and length of the filaments formed. A definitely filamentous type which is commonly referred to as "spider" colony may be considered most characteristic of *Actinomyces israelii* and many strains of *Actinomyces gerencseriae* and *Actinomyces hordeovulneris* (Figure 28). This microcolony consists of branching threads which often appear to originate from a single, central point with radial symmetry. The filaments are slender and moderately long with branches arising at an acute angle (Slack and Gerencser, 1975). In certain strains, the microcolonies may be smaller consisting of only one or two branched filaments (Figure 29), or the colonies may be larger with many radial threads which cross and fragment to bacillary elements at the center (Figure 30). Occasionally, small colonies with few, short projecting filaments and a fragmented center are seen (Schaal and Pulverer, 1981; Schaal et al., 2006; Slack and Gerencser, 1975) (Figure 31).

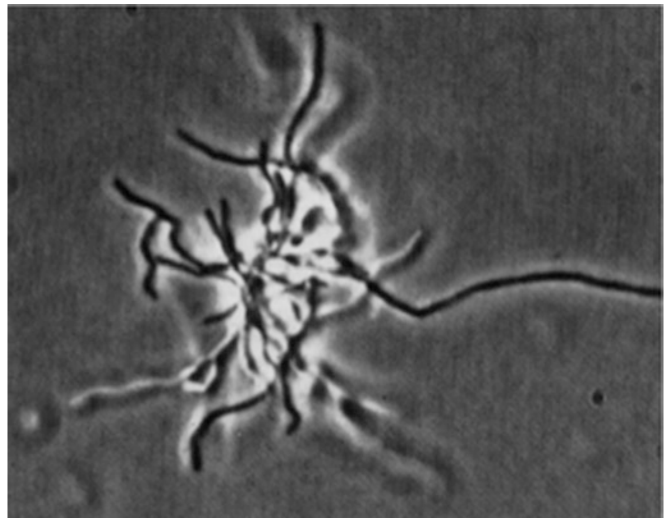

FIGURE 28. *Actinomyces gerencseriae.* Spider-like, highly filamentous microcolony on BHIA (slide culture, 26 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1500×).

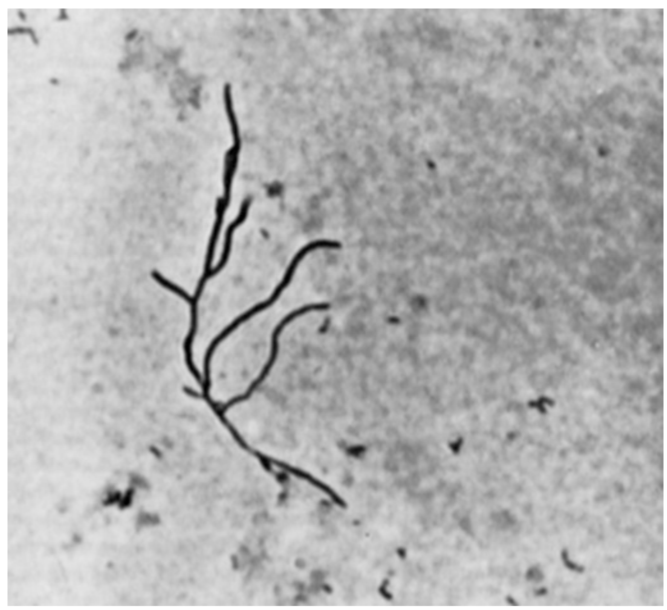

FIGURE 29. *Actinomyces gerencseriae.* Microcolony on BHIA, showing a long filament with many branches (slide culture, 24 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1200×).

*CC-medium (Heinrich and Korth, 1967) : I. Solution of minerals and trace elements, containing per liter of distilled water (can be stored in refrigerator for months): $MgSO_4 \cdot 7H_2O$, 20 g; $CaCl_2 \cdot 2H_2O$, 2 g; $FeSO_4 \cdot 7H_2O$, 400 mg; $MnSO_4 \cdot 2H_2O$, 15 mg; $NaMoO_4 \cdot 2H_2O$, 15 mg; $ZnSO_4$, 4 mg; $CuSO_4 \cdot 5H_2O$, 0.4 mg; $CoCl_2 \cdot 4H_2O$, 0.4 mg; boric acid, 20 mg; KI, 10 mg. The solution is acidified with 10 ml 10% HCl. *II. Vitamin solution*, containing per 100 ml of distilled water (should be prepared freshly): thiamine-HCl, 20 mg; pyridoxine-HCl, 20 mg; biotin, 1 mg; folic acid, 5 mg; vitamin B_{12} (1 mg/100 ml), 1 ml; *p*-aminobenzoic acid, 20 mg; *m*-inositol, 20 mg; nicotinamide, 10 mg; nicotinic acid, 10 mg; Ca-pantothenate, 20 mg. III. Solution of amino acids and vitamins, containing per 100 ml of distilled water (should always be prepared freshly): casein hydrolysate, 12 g; L-cysteine-HCl, 500 mg; L-asparagine, 30 mg; DL-tryptophan, 20 mg; solution II, 12 ml. Solution III is sterilized by Seitz filtration. Preparation of the final medium: KH_2PO_4, 4 g, is dissolved in 250 ml of distilled water and adjusted to pH 7.6 with NaOH. Then, 10 ml of solution I, 500 mg of potato starch dissolved in 70 ml of boiling distilled water, about 20 g of agar (depending on quality), and distilled water are added to give a final volume of 900 ml. The mixture is autoclaved at 121°C for 15 min. After cooling to 50°C, solution III is added aseptically and the final pH adjusted to 7.3. The medium is poured in 15-ml amounts into glass Petri dishes.

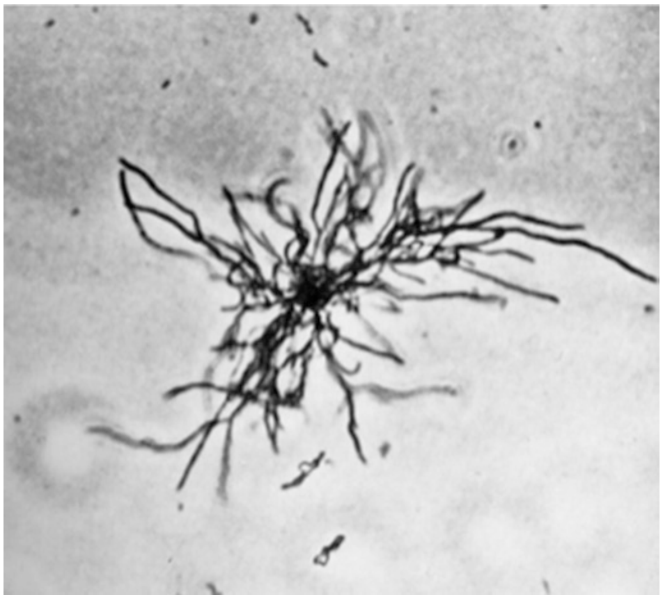

FIGURE 30. *Actinomyces israelii.* Spider- or cobweb-like microcolony on BHIA with beginning fragmentation in the center (slide culture, 48 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1200×).

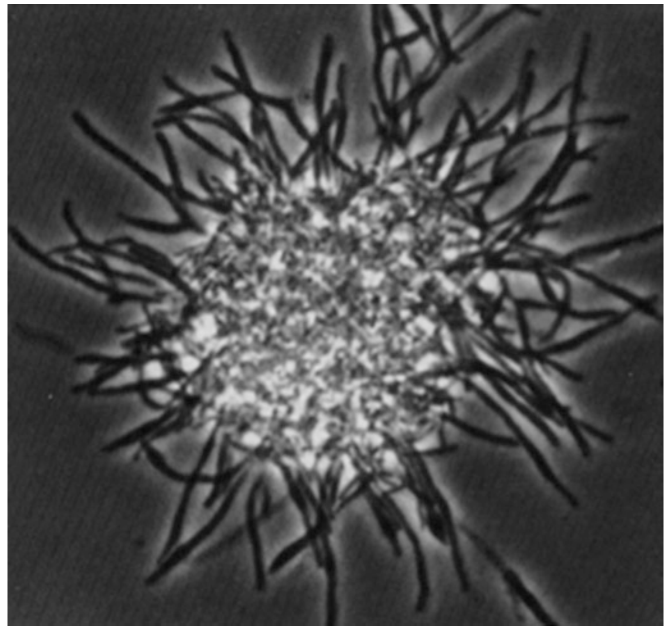

FIGURE 32. *Actinomyces naeslundii.* Filamentous microcolony on BHIA with numerous rigidly projecting filaments (slide culture, 24 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1600×).

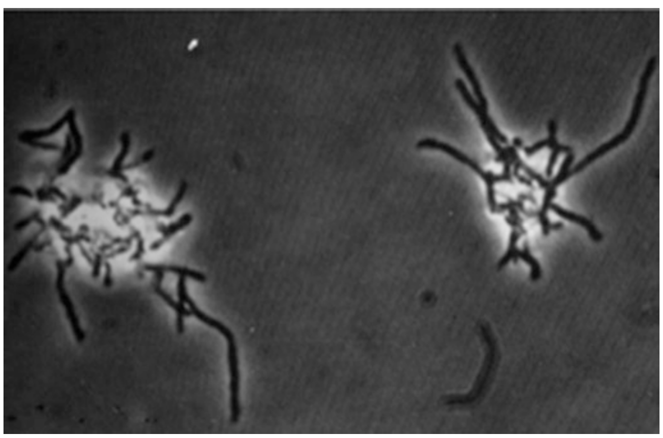

FIGURE 31. *Actinomyces gerencseriae.* Spider-like microcolony on BHIA with comparatively short filaments (slide culture, 24 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1600×).

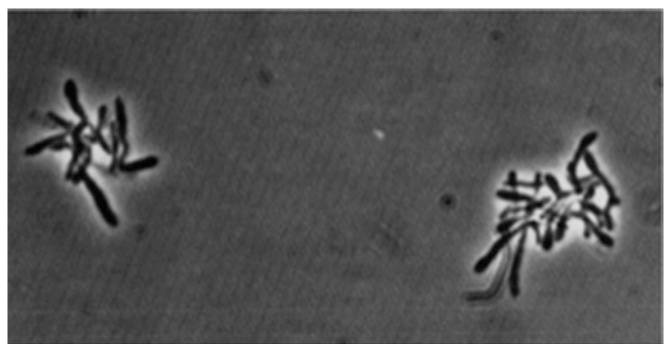

FIGURE 33. *Actinomyces oris (Actinomyces viscosus,* serovar II). Microcolony on BHIA consisting of short filaments with clubbed ends, grown under strictly anaerobic conditions (slide culture, 24 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1600×).

Actinomyces naeslundii and, more characteristically, fresh hamster isolates of *Actinomyces viscosus* usually produce filamentous microcolonies. In very early growth stages, these may resemble the spider colonies of *Actinomyces israelii* (Coleman et al., 1969; Howell, 1963; Howell et al., 1959, 1965; Locci and Schaal, 1980). However, after 18–24 h of incubation, *Actinomyces naeslundii* microcolonies are usually larger than those of *Actinomyces israelii* and have a dense center composed of diphtheroidal cells and/or partly fragmented filaments which are surrounded by long, branched, and irregularly curved threads projecting in all directions (Schaal and Pulverer, 1981; Slack and Gerencser, 1975) (Figure 32). Occasionally, the filamentous fringe may be very short.

In principle, the microcolonies of human and hamster isolates of *Actinomyces viscosus* (*Actinomyces oris* and *Actinomyces viscosus sensu stricto*) resemble those of *Actinomyces naeslundii* presenting as dense cores with a filamentous periphery. However, the projecting threads are often shorter or even very short (Slack and Gerencser, 1975), and the colonies may be small when the organisms (*Actinomyces viscosus* serovar II = *Actinomyces oris*; *Actinomyces viscosus sensu stricto*) are cultured under anaerobic conditions (Figure 33). Spider-like very young microcolonies have also been reported (Howell, 1963). After serial laboratory subcultivation, both *Actinomyces viscosus sensu stricto* and *Actinomyces viscosus* serovar II (*Actinomyces oris*) tend to produce "smooth" microcolonies which are circular and have a smooth or granu-

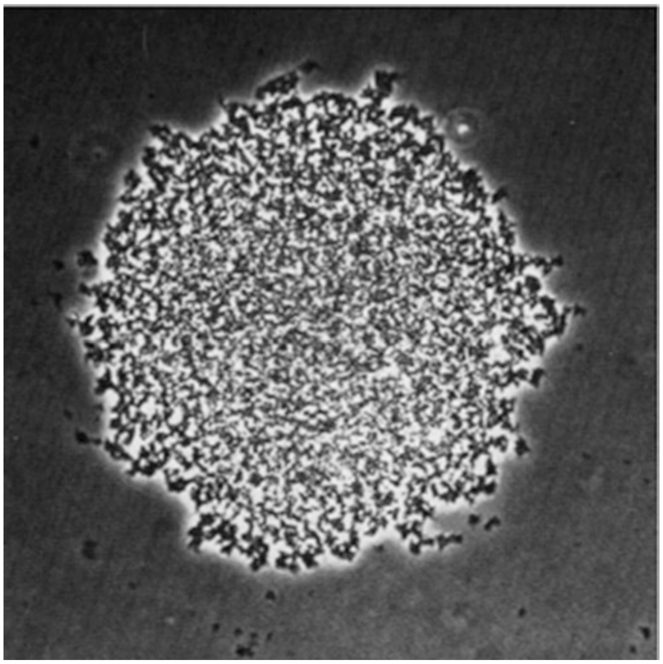

FIGURE 34. *Actinomyces viscosus.* Microcolony on BHIA chiefly consisting of short rods, grown under aerobic conditions with added CO_2 (slide culture, 48 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (200×).

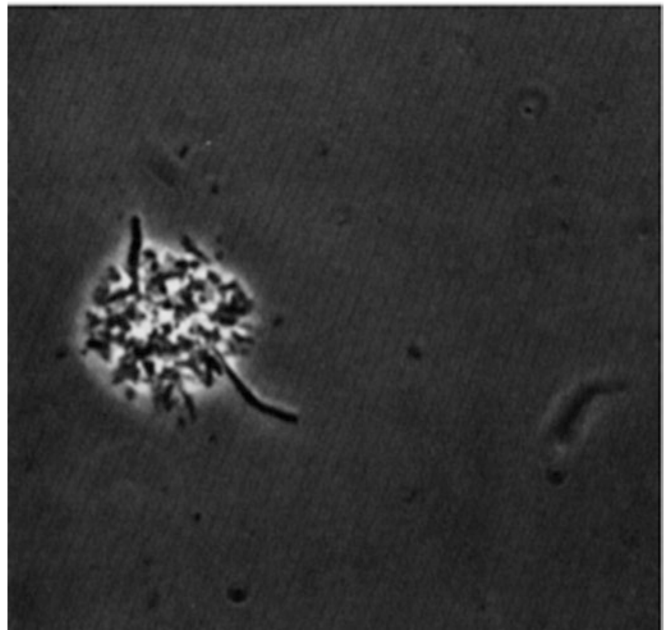

FIGURE 35. *Actinomyces bovis*, serovar I. Microcolony on BHIA, consisting of a few filaments and short rods (slide culture, 24 h at 36°C); phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1200×).

lar surface and an entire or irregular edge (Slack and Gerencser, 1975) (Figure 34). In such predominantly smooth cultures, a few filamentous colonies may be present. The heterogeneous picture resulting from this morphological dissociation is easily mistaken for contamination of the culture.

Actinomyces bovis, *Actinomyces denticolens*, *Actinomyces hyovaginalis*, *Actinomyces marimammalium*, *Actinomyces meyeri*, *Actinomyces nasicola*, *Actinomyces neuii*, *Actinomyces odontolyticus*, *Actinomyces radicidentis*, *Actinomyces radingae*, *Actinomyces slackii*, *Actinomyces suimastitidis*, *Actinomyces turicensis*, and *Actinomyces vaccimaxillae* all form predominantly or exclusively non-filamentous microcolonies. These have a smooth or finely granular surface, an entire or irregular edge, are slightly raised to convex, white to colorless and soft, and may show a few short projecting filaments (Figure 35, Figure 36, and Figure 37). In addition, they may have an optically dark central spot, and typical *Actinomyces bovis* microcolonies often have irregular, jagged edges, but do not show radiating filaments (Slack and Gerencser, 1975). Similar colonies, occasionally with a dark center, are produced by *Actinomyces denticolens* (Figure 38). Nevertheless, truly filamentous strains have been reported for both *Actinomyces bovis* (Figure 39) and *Actinomyces odontolyticus* (Georg et al., 1964; Pine et al., 1960; Slack and Gerencser, 1975) and may also occur in *Actinomyces denticolens* (Figure 40). Completely smooth, circular microcolonies with entire edges are characteristic of *Actinomyces hyovaginalis*, *Actinomyces marimammalium*, *Actinomyces meyeri*, *Actinomyces nasicola*, *Actinomyces neuii*, *Actinomyces radicidentis*, *Actinomyces radingae*, *Actinomyces slackii*, *Actinomyces suimastitidis*, *Actinomyces turicensis*, and *Actinomyces vaccimaxillae* although the majority of the recently described new *Actinomyces* species have not been characterized in detail as far as their microcolony morphology is concerned.

massiliensis, *Actinomyces oricola*, and *Actinomyces urogenitalis* is not available (Schaal et al., 2006).

The morphological properties of microcolonies of the "classical" *Actinomyces* species, as demonstrated by light microscopy, have been confirmed and elucidated in more detail by scanning electron microscopy (Locci, 1976, 1978; Slack and Gerencser, 1975). A sharp contrast was noted between the compact non-filamentous colonies of *Actinomyces bovis* and *Actinomyces odontolyticus* and the filamentous ones of *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato.*

Colonies of the "classical" *Actinomyces* species mature within 5–14 d of incubation on BHIA at 36±1°C. The colony

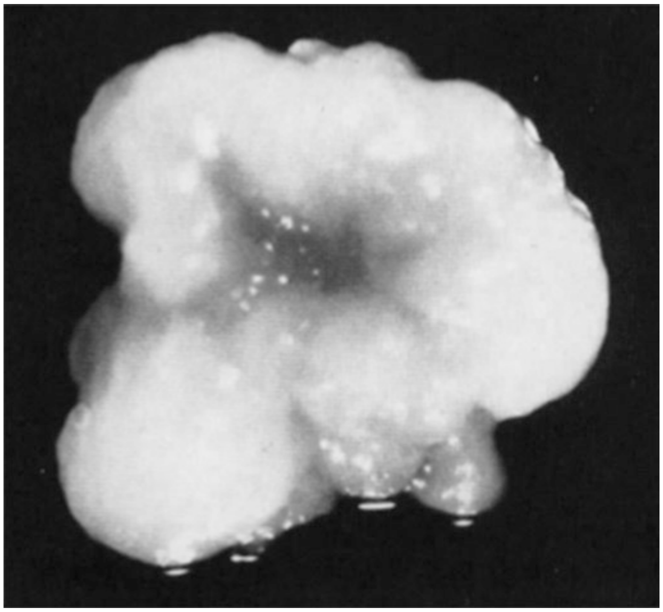

FIGURE 41. *Actinomyces israelii.* Mature "molar-tooth" colony on CC-medium (14 d at 36°C); micrograph (30×).

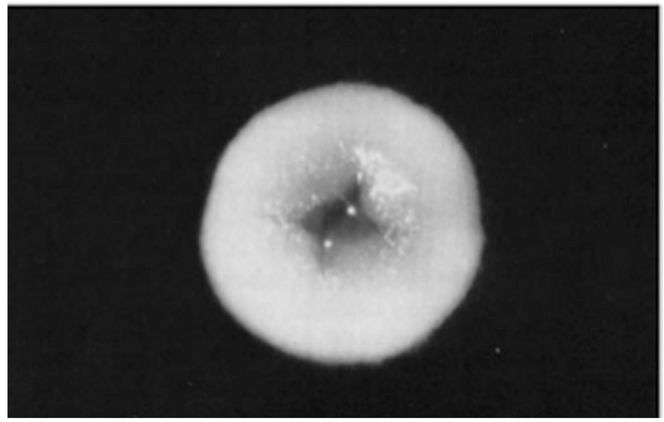

FIGURE 42. *Actinomyces israelii.* Mature colony with central depression on CC-medium (14 d at 36°C); micrograph (30×).

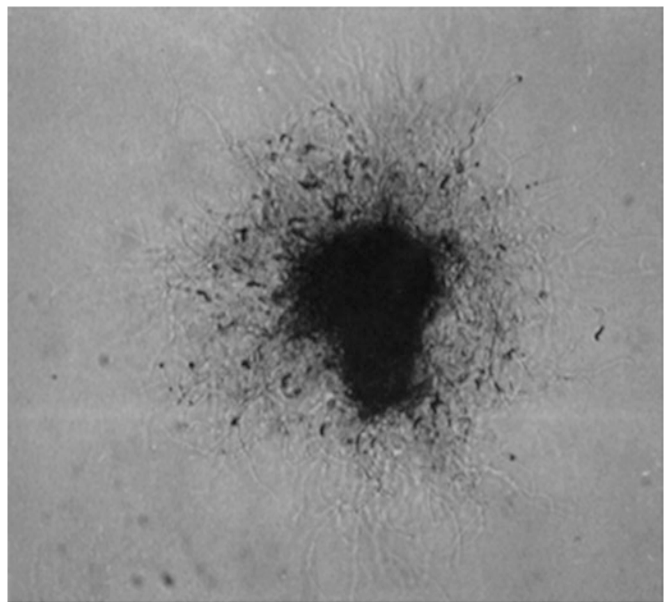

FIGURE 43. *Actinomyces gerencseriae.* Small mature colony on CC-medium with a highly filamentous fringe and short aerial hyphae (dark parts of the filaments [14 d at 36°C]); micrograph (200×).

morphology may slightly differ when growth on BHIA is compared with that on CC medium (Heinrich and Korth, 1967) or on blood agar, but the general growth characteristics may be observed on either medium. Strains which produce highly filamentous microcolonies usually form rough mature colonies. The morphology of the recently published new *Actinomyces* species has only been described in some detail after 24–48 h of incubation, predominantly on media containing blood. Details on the colony morphology of *Actinomyces canis* (Hoyles et al., 2000), *Actinomyces coleocanis* (Hoyles et al., 2002a), *Actinomyces massiliensis* (Renvoise et al., 2009), *Actinomyces radicidentis* (Collins et al., 2000), *Actinomyces suimastitidis* (Hoyles et al., 2001a), and *Actinomyces urogenitalis* (Nikolaitchouk et al., 2000), were not given in the original descriptions of these species, except that the colonies of *Actinomyces radicidentis* may be brownish and those of *Actinomyces urogenitalis* reddish (Schaal et al., 2006).

Mature colonies of *Actinomyces israelii* and *Actinomyces gerencseriae* are 0.5–2.0 mm in diameter, opaque, and white to gray-white in color. Rough colonies, with or without central depressions, are considered most characteristic of *Actinomyces israelii* and have been described as molar-tooth, bread-crumb, or raspberry-like colonies (Schaal and Pulverer, 1981; Slack and Gerencser, 1975) (Figure 41 and Figure 42). These colonies are circular to irregular in shape with undulate, lobate, or erose edges and, often, with a highly filamentous fringe (Figure 43). In addition, they are convex, pulvinate, or umbonate with a convoluted or granular surface and a dry to crumbly texture. Although *Actinomyces gerencseriae* may show the same colonial picture, this closely related species tends to produce more often smooth mature colonies with entire, circular or irregular edges, a white to gray-white to creamy-white, opaque appearance, and soft texture (Schaal and Pulverer, 1981; Slack and Gerencser, 1975) (Figure 44), which is comparatively rarely seen in *Actinomyces israelii.* The surface of this colony type is usually shiny, but may also be granular and matte. Rough *Actinomyces gerencseriae* and *Actinomyces israelii* colonies may be very hard and they often adhere to the agar medium or come off *in toto* when an attempt is made to pick them. Soft and certain bread-crumb colonies, on the other hand, are friable and easy to disintegrate or remove from the agar surface.

Although the formation of aerial hyphae is by no means characteristic of the genus, a few *Actinomyces gerencseriae* and *Actinomyces israelii* isolates from various sources may produce numerous, short aerial filaments (Figure 43) especially when grown on comparatively poor agar media (Erikson, 1940; Locci, 1978; Schaal, 1986b; Slack and Gerencser, 1975).

Mature colonies of *Actinomyces hordeovulneris* are similar to those of *Actinomyces israelii.* On bovine blood agar, this species produces white, agar-adherent, molar toothed colonies with a tendency to shift to a white, conical, domed, buttery, less adherent type upon

laboratory passage. Diameters are 0.5–1.0 mm after 48 h at 37°C and 2 mm after 3 d (Buchanan et al., 1984).

Macrocolonies of *Actinomyces naeslundii sensu lato* are predominantly soft, circular, low convex to umbonate, and entire measuring 1.0–5.0 mm in diameter (Figure 45 and Figure 46). Their color is white to gray- or creamy-white and the surface structure is usually granular. Frequently, some peripheral projecting filaments or even mycelial structures can be observed under the microscope (Figure 47) and often show an asymmetrical distribution. Furthermore, various degrees of roughness may be found so that isolates may appear in the bread-crumb or molar-tooth colony type (Figure 48).

Mature colonies of *Actinomyces viscosus sensu lato* grown under reduced oxygen tension for 7 d are approximately 0.5 mm in diameter while cultures incubated aerobically with added CO_2 produce larger colonies (4–5 mm in diameter). Their color is creamy-white, the texture is usually soft and may be viscous, in both animal (Howell, 1963) and human isolates. The overall picture is very similar to that described for *Actinomyces naeslundii sensu lato* (Figure 49 and Figure 50) although hamster isolates

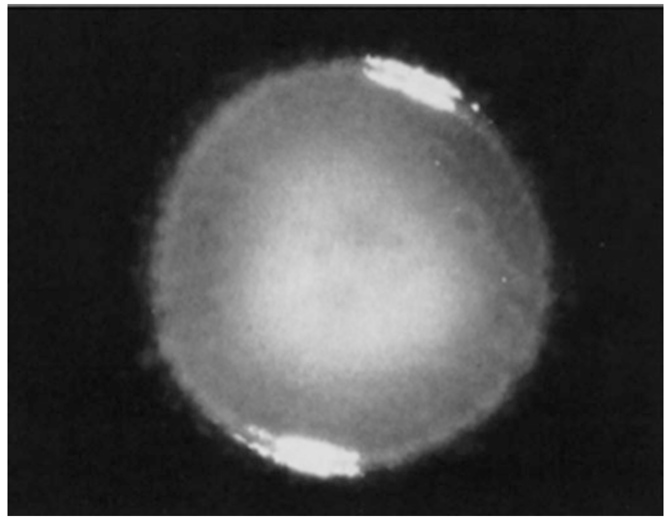

FIGURE 50. *Actinomyces oris* (*Actinomyces viscosus*, serovar II). Mature colony on CC-medium with a smooth, shiny surface and an irregular, "fuzzy" edge (14 d at 36°C); micrograph (30×).

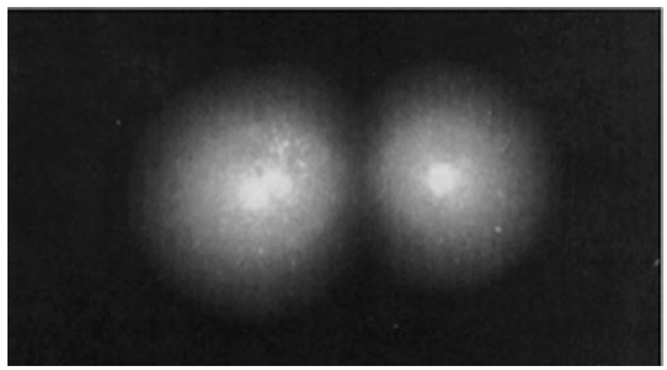

FIGURE 51. *Actinomyces bovis*, serovar I. Mature colony on CC-medium with a smooth to finely granular surface and an entire edge (14 d at 36°C); micrograph (30×).

(*Actinomyces viscosus sensu stricto*) with short, scattered aerial filaments have been reported (Slack and Gerencser, 1975). Completely smooth colonies may resemble those of cutaneous propionibacteria.

The typical macrocolony of *Actinomyces bovis* measures 0.5–1.0 mm in diameter and is circular, convex, entire, white, and predominantly soft, with a smooth or finely granular surface and a dark center (Figure 51). Rough mature colonies (Figure 52) may resemble the molar-tooth or bread-crumb colony type of *Actinomyces israelii* (Slack and Gerencser, 1975).

Actinomyces odontolyticus forms mature colonies which are 1.0–2.0 mm in size, circular to irregular with an entire or irregular edge, low convex to umbonate with a smooth to finely granular surface and a soft texture (Figure 53). In transmitted light, they may show a dark center spot and/or dark irregular granules which decrease in size from the center to the periphery (Figure 54). Rough strains may have a colony morphology similar to that of *Actinomyces israelii*. On BHIA, macrocolonies of *Actinomyces odontolyticus* are opaque and white. However, older colonies grown on blood agar develop a deep red color (Batty, 1958). This pigment may appear during anaerobic incubation in as little as 48 h, but it usually requires 5–10 d to develop or it may only be formed after the cultures have been left standing in air at room temperature following primary anaerobic incubation (Slack and Gerencser, 1975). Occasionally, the pigment formation cannot be demonstrated.

Mature colonies of *Actinomyces denticolens* reach at least 2.0 mm in diameter and are circular, entire, convex, or umbonate and smooth (Figure 55). On horse blood agar, they develop a slightly pink pigmentation when grown anaerobically, but they are white if grown in air (Dent and Williams, 1984b).

On horse blood agar plates after 3–5 d of anaerobic incubation at 37°C, colonies of *Actinomyces howellii* are white, smooth,

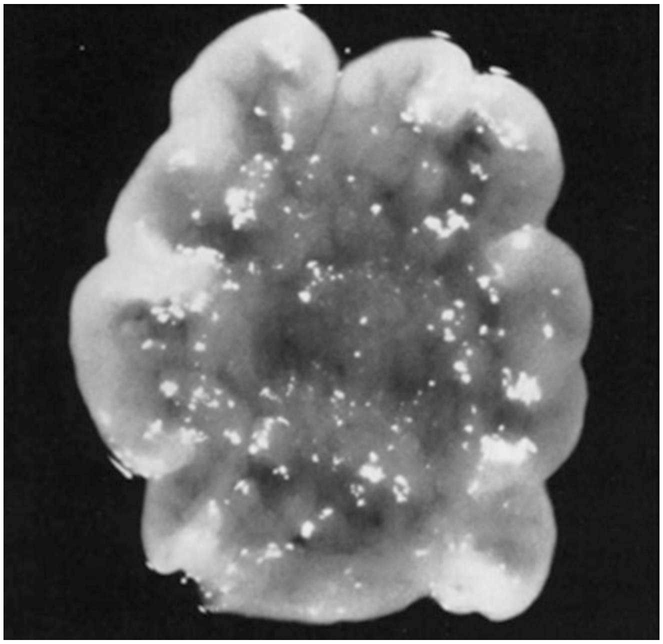

FIGURE 52. *Actinomyces bovis*, serovar II. Bread-crumb colony on CC-medium with a highly uneven surface and an irregular, lobate edge (14 d at 36°C); micrograph (30×).

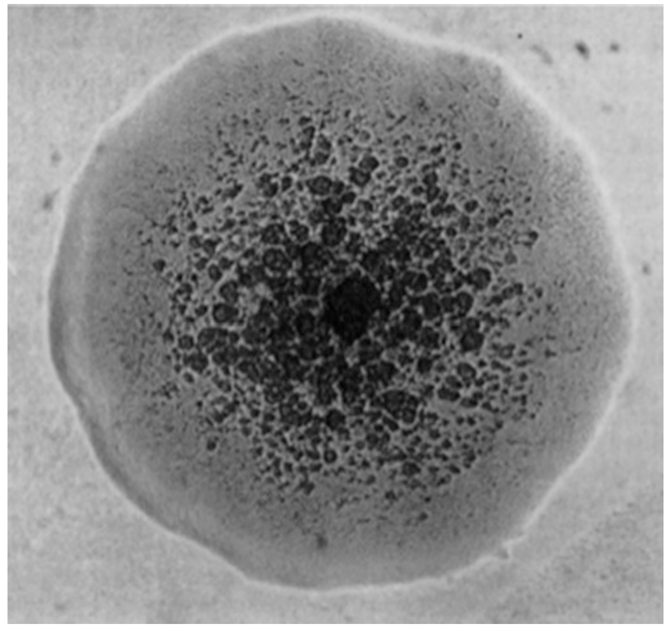

FIGURE 54. *Actinomyces odontolyticus*, serovar I. Mature colony on CC-medium with a dark center spot and granular inclusions decreasing in size from the center to the periphery (14 d at 36°C); micrograph in transmitted light (120×).

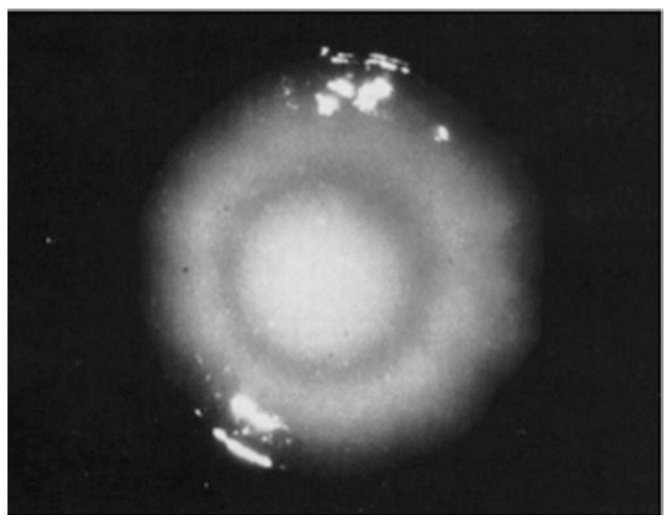

FIGURE 55. *Actinomyces denticolens*. Mature umbonate colony on CC-medium with a shiny surface and an irregular edge (14 d at 36°C); micrograph (30×).

shiny, translucent, and convex with entire margins. Their diameter is up to 2 mm (Dent and Williams, 1984c).

Mature surface colonies of *Actinomyces meyeri* on supplemented BHI blood agar are pinpoint to 1 mm in diameter, circular, flat to convex, translucent to opaque and white with shiny, smooth surfaces and entire margins. They may be α- or non-hemolytic (Cato et al., 1984). In transmitted light, their appearance is similar to those of *Actinomyces odontolyticus*. On horse blood agar after 3–5 d of incubation at 37°C, colonies of *Actinomyces slackii* are white, smooth, shiny, translucent, and convex, having entire margins and measuring up to 2 mm in diameter (Dent and Williams, 1986). Colonies of *Actinomyces georgiae*, incubated anaerobically, are 0.5–2 mm in diameter, usually circular, entire, low convex, opaque (smaller colonies are transparent to translucent), white (27% were described as tan or beige), shiny, and smooth (Johnson et al., 1990). Colonies of *Actinomyces radingae* on sheep blood agar are small (0.3–0.5 mm in diameter), gray, circular, low convex, with a glistening surface, opaque, of a butyrous consistency and with an entire edge after 48-h aerobic incubation with 5% added CO_2. Growth on sheep blood agar is the same under aerobic conditions with added CO_2 and under anaerobic conditions. A hemolytic zone appears slowly and starts mostly with α-hemolysis (Vandamme et al., 1998; Wüst et al., 1995a). Colonies of *Actinomyces turicensis*, grown on sheep blood agar aerobically with 5% CO_2 for 48 h,

are also small, gray, circular, convex, with a glistening surface, opaque, with a butyrous consistency and an entire edge. They produce a small zone of β-hemolysis, especially when grown under CO_2 enrichment or anaerobically, and growth under these conditions is slightly better compared to aerobiosis (Vandamme et al., 1998).

Within the species *Actinomyces hyovaginalis*, two biovars ("vaginal" biovar and "general" biovar) have been discerned which chiefly differ in colony morphology and a few physiological reactions (Storms et al., 2002). When grown on horse blood agar in an anaerobic or CO_2-enriched atmosphere, colonies of the "vaginal" biovar of *Actinomyces hyovaginalis* are flat with outrunning edges and non-hemolytic (Collins et al., 1993). The "general" biovar is characterized by smaller colonies that are more convex than those of the "vaginal" type and which lack the characteristic outrunning edges of the latter type resembling colonies of *Arcanobacterium pyogenes* apart from being non-hemolytic or at best weakly hemolytic (Storms et al., 2002).

Actinomyces neuii subsp. *neuii* forms circular, smooth, convex, opaque colonies, more white than creamy in color, and with entire edges. Their size is 0.5–1.5 mm in diameter after 48 h of incubation in 5% CO_2 on sheep blood agar. Most strains produce α-hemolysis on sheep blood agar and all strains do so on human blood agar. The colonies of *Actinomyces neuii* subsp. *anitratus* are similar to those of the subspecies *neuii*, except that the latter are non-hemolytic (Funke et al., 1994).

Colonies of *Actinomyces europaeus* were described as circular and smooth with a translucent grayish appearance. After 48 h of incubation in 5% CO_2-enriched atmosphere at 37°C, they measure not more than 0.5 mm in diameter (Funke et al., 1997a). Grown on blood agar in the presence of 5% CO_2 for 24 h, *Actinomyces graevenitzii* produces non-hemolytic, opaque colonies which measure approximately 0.2 mm in diameter. They characteristically adhere to agar surfaces (Pascual Ramos et al., 1997a). *Actinomyces bowdenii* forms non-hemolytic, grayish-white, rounded colonies after 24–48 h of aerobic incubation on blood agar at 37°C. Their diameter is approximately 2 mm. Growth is not enhanced by increased concentrations of CO_2 between 1.5 and 10% (Pascual et al., 1999). After 48 h of incubation on blood agar, colonies of *Actinomyces marimammalium* are gray, entire, circular, convex, and pinpoint to 0.5 mm in diameter. Hemolysis is not observed (Hoyles et al., 2001c). *Actinomyces catuli* produces tiny, irregular, convex, white colonies adherent to the medium at colony base (Hoyles et al., 2001b). When grown on Columbia blood agar for 24 h, colonies of *Actinomyces funkei* are small (<1 mm in diameter), non-hemolytic, and gray in color (Lawson et al., 2001b). On Fastidious Anaerobe Agar with 5% horse blood after 48 h of incubation, colonies of *Actinomyces cardiffensis* are pinpoint, convex, smooth-surfaced, entire-edged, and opaque cream to pinkish. As most other *Actinomyces* species, they are non-hemolytic (Hall et al., 2002). *Actinomyces hongkongensis* forms non-hemolytic, pinpoint colonies after 24 h of incubation at 37°C on sheep blood agar in an anaerobic atmosphere (Woo et al., 2003). Colonies of *Actinomyces vaccimaxillae* are <1 mm in diameter, convex, smooth, entire-edged, opaque white, and non-hemolytic when grown anaerobically on Fastidious Anaerobe Agar with 5% horse blood for 48 h (Hall et al., 2003a). After 48 h of anaerobic incubation on Fastidious Anaerobe Agar, colonies of *Actinomyces nasicola* are pinpoint, white or gray, opaque, shiny, entire, and convex (Hall et al., 2003d). Under analogous growth conditions on Fastidious Anaerobe Agar with 5% horse blood, *Actinomyces oricola* forms pinpoint, breadcrumb-like, white, and non-hemolytic colonies (Hall et al., 2003c). *Actinomyces dentalis* produces tiny, white, breadcrumb-like, agar-pitting colonies on Fastidious Anaerobe Agar with 5% horse blood after 48 h of anaerobic incubation (Hall et al., 2005). Colonies of *Actinomyces ruminicola* when grown on PYRG agar (peptone-yeast extract-glucose agar with 15% rumen fluid) for 48 h at 46°C are circular, slightly convex, white, and measure approximately 0.5–0.8 mm in diameter (An et al., 2006). *Actinomyces massiliensis* was reported to produce circular, white, shiny, pinpoint colonies after 48 h of anaerobic incubation at 37°C on sheep blood agar (Renvoise et al., 2009). In liquid media (e.g., thioglycolate broth or Tarozzi broth*), *Actinomyces* species either grow as discrete compact masses of variable size leaving the medium clear, or they produce a diffuse growth with varying amounts of a granular, flaky, or pellicular sediment (Schaal, 1986b; Slack, 1974). The cotton pad- or snowball-like growth, which represents filamentous colonies and may be suspended in the broth or adhere to the glass or the surface of the liver piece (Figure 56), is commonly seen

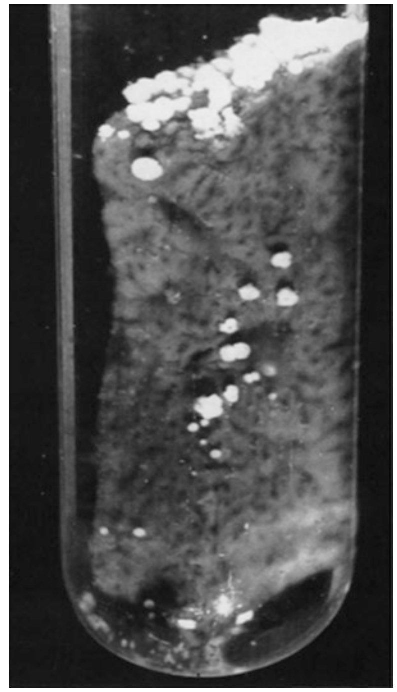

FIGURE 56. *Actinomyces israelii.* Mature snowball- or cotton pad-like colonies adhering to the liver piece in Tarozzi broth (14 d at 36°C) (2.5×).

*Tarozzi broth, modified according to Schaal et al. (2006): I: Basal nutrient broth: meat extract, 10 g; peptone (e.g., peptone P – Oxoid), 12 g; NaCl, 3 g; K_2HPO_4, 2 g; distilled water to equal a total of 1 liter. Dissolve the ingredients under heat at 80°C and boil subsequently for 20 min. Adjust the pH to 7.5 with NaOH solution. II. Preparation of liver pieces: Cut fresh guinea pig or beef liver into pieces of approximately 2 × 1 × 1 cm and wash them thoroughly in several changes of fresh saline. III. Preparation of the medium: Place liver pieces into test tubes (1 piece per tube). Add 8 ml of broth I supplemented with 0.1% sodium thioglycolate (w/v) to each tube. Stopper the tubes with cotton plugs and sterilize by autoclaving at 121°C for 15 min. Inoculate immediately after cooling, seal the tubes by adding about 1 ml of sterilized melted petrolatum (petroleum jelly, Vaseline) or paraffin wax (less suitable), and incubate at 36±1°C.

in *Actinomyces gerencseriae* and *Actinomyces israelii* strains, but also in rough filamentous isolates of other species. Broth cultures of *Actinomyces bovis*, *Actinomyces denticolens*, *Actinomyces meyeri*, *Actinomyces odontolyticus*, and *Actinomyces viscosus sensu lato* are often evenly turbid and, upon further incubation, may show a granular, flocculent, pellicular, stringy, or smooth sediment. Many strains of *Actinomyces viscosus sensu stricto* and a few *Actinomyces bovis* and *Actinomyces gerencseriae* isolates produce a viscous growth which, in the case of *Actinomyces viscosus sensu stricto*, may give rise to a mucoid sediment (Howell, 1963). Cultures of *Actinomyces meyeri* in peptone-yeast extract-glucose broth are only slightly turbid with a smooth or stringy sediment (Cato et al., 1984). Growth of *Actinomyces hordeovulneris* in trypticase soy broth supplemented with ≥5% fetal calf serum is flocculent, but weak without added serum (Buchanan et al., 1984). Cultures of *Actinomyces georgiae* in pre-reduced anaerobically sterilized peptone-yeast extract-glucose-Tween 80 broth were described as being predominantly turbid (85%) with smooth (38%), flaky (26%), crumbly or granular (24%), or stringy to ropy (12%) sediment that occasionally adheres to the bottom of the tube. Broth cultures without turbidity often have a crumbly to coarse granular sediment (Johnson et al., 1990). Details on the appearance of broth cultures of the remaining *Actinomyces* species have not been published.

Life cycle. Filamentous *Actinomyces* strains show a characteristic life cycle when cultivated on or in artificial media. The initial developmental step includes elongation of the original, usually rod-shaped propagule by apical growth at one or both ends and possibly lateral budding (Locci and Schaal, 1980; Morris, 1951) (Figure 57). When growth proceeds, a network of interwoven, branching filaments may form whose central parts sooner or later exhibit signs of septation and fragmentation (Figure 28, Figure 30, Figure 31, Figure 32, and Figure 40). Degree of filament formation, as well as intensity and rate of fragmentation and cell separation vary depending on species and strain peculiarities so that it may sometimes be difficult to detect the developmental cycle. Variation in filament formation and fragmentation results in mature colonies which either remain predominantly or partly filamentous (Figure 42, Figure 43, and Figure 47) and have a rough appearance and a dry to crumbly or even very hard texture or become smooth and soft (Figure 45, Figure 46, Figure 51, Figure 53, Figure 54, and Figure 55) being composed of bacillary or coccobacillary forms only. In addition, various transitions between these extremes may be found.

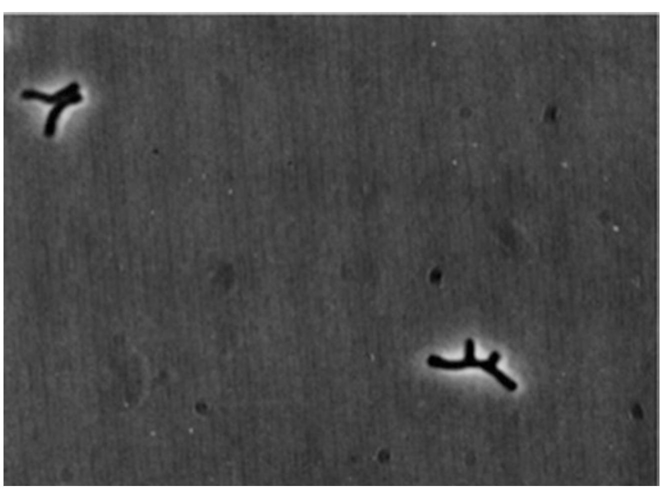

FIGURE 57. *Actinomyces odontolyticus*, serovar I. Filament with signs of budding in a very young (16 h) slide culture; phase-contrast micrograph *in situ* in lactophenol cotton blue mounting fluid (1600×).

Nutrition and growth conditions. The minimal nutritional requirements of *Actinomyces* species are not well understood. However, good growth has only been obtained on or in complex media containing either rich biological ingredients (e.g., BHI, meat extract, yeast extract, and serum) or a defined and complex mixture of a large variety of organic and inorganic compounds. Studies using synthetic media were reported (Christie and Porteous, 1962a, 1962b, 1962c; Howell and Pine, 1956; Keir and Porteous, 1962), but were mostly restricted to a few strains. Modifications and/or simplifications of the synthetic medium of Howell and Pine (1956) have been developed (Georg et al., 1964; Heinrich and Korth, 1967; Pine and Watson, 1959) and were tested with a greater number of strains. Attempts to further simplify these media have so far always resulted in insufficient growth rates or rapid loss of cultures during subcultivation.

It can, therefore, be concluded that the anabolic capacity of *Actinomyces* species is rather limited (Slack and Gerencser, 1975). These organisms apparently require organic nitrogen (e.g., peptides, amino acids), a fermentable carbohydrate and possibly also vitamins and other growth factors (e.g., Tween 80) for optimum growth. *Actinomyces meyeri* was found to have an absolute requirement for vitamin K_1, and its replication is greatly stimulated by 0.02% Tween 80 and by a fermentable carbohydrate (Cato et al., 1984). Serum added to the medium also enhances growth of this organism. The same is true for *Actinomyces hordeovulneris* whose growth is considerably stimulated when the medium is supplemented with 10–20% (v/v) fetal calf serum (Buchanan et al., 1984). Addition of 0.02% Tween 80 to broth media also enhanced growth and carbohydrate fermentation of the majority (62%) of the *Actinomyces georgiae* strains tested (Johnson et al., 1990). On the other hand, purines, pyrimidines, and potential other growth factors were found to be either stimulatory or inhibitory to the replication of certain *Actinomyces* strains (Christie and Porteous, 1962a; Keir and Porteous, 1962). For example, one strain of *Actinomyces israelii* apparently required adenine and thymine to be added to the simplest medium while another strain of the same species was inhibited by one or more of the bases guanine, xanthine, and uracil (Christie and Porteous, 1962a).

Though the nutritional requirments of all *Actinomyces* species described during the last two decades have not been characterized, essentially all of them grow only on complex media such as trypticase soy, Columbia, BHI, or Fastidious Anaerobe Agar usually supplemented with sheep, horse, or human blood (Buchanan et al., 1984; Hall et al., 2003a, 2003c, 2003d; Lawson et al., 2001b; Pascual et al., 1999). *Actinomyces ruminicola* was primarily isolated by inoculating rumen content into the xylan medium of Krause et al. (2001) and subsequently subcultured in or on peptone-yeast extract-glucose media containing 15% rumen fluid (PYRG with or without agar). Whether rumen fluid is an obligate additive for good growth of this organism remains to be seen.

Fermentable carbohydrates are the preferred sources of carbon and energy and are therefore usually necessary for optimum growth. When utilized, they are fermented with the production of short-chain fatty acids but no gas (Howell et al., 1959; Lentze, 1938a; Schaal et al., 2006; Slack, 1974; Slack and Gerencser, 1975). Mono-, di-, tri-, and polysaccharides, as well as sugar alcohols and glucosides, may serve as fermentable substrates, however, with considerable species differences so that carbohydrate fermentation patterns form the traditional basis for phenotypic differentiation of these actinomycetes and related bacteria (Table 4, Table 5, Table 7, and Table 9). Only *Actinomyces johnsonii*, *Actinomyces naeslundii sensu stricto*, and *Actinomyces oris*, which were formally described recently (Henssge et al., 2009), as well as *Actinomyces viscosus sensu stricto*, cannot be differentiated reliably using phenotypic characteristics (Johnson et al., 1990) although it remains to be clarified whether more carefully adapted techniques could overcome this problem.

Glucose and fructose are utilized by nearly all of the organisms currently included in the genus *Actinomyces* (Schaal et al., 2006; Schofield and Schaal, 1979a, 1979b, 1980, 1981; Slack, 1974; Slack and Gerencser, 1975). However, *Actinomyces hongkongensis* was reported to be unable to produce acid from glucose (Woo et al., 2003) and even appeared to be completely asaccharolytic (Table 4 and Table 7). *Actinomyces nasicola* was found to produce acid from glucose, cellobiose, and fructose but not from a large variety of other carbohydrates (Hall et al., 2003d) (Table 4 and Table 7). Detectable acid production from carbohydrates does not only depend on the presence of the respective enzymes in the species in question, but also on the test procedure used and especially on the relation between inoculum size and substrate volume.

Members of the genus *Actinomyces* vary considerably with respect to their oxygen requirements. *Actinomyces bowdenii* (Pascual et al., 1999), *Actinomyces canis* (Hoyles et al., 2000), *Actinomyces cardiffensis* (Hall et al., 2002), *Actinomyces catuli* (Hoyles et al., 2001b), *Actinomyces coleocanis* (Hoyles et al., 2002a), *Actinomyces denticolens* (Dent and Williams, 1984b), *Actinomyces europaeus* (Funke et al., 1997a), *Actinomyces funkei* (Lawson et al., 2001b), *Actinomyces georgiae* (Johnson et al., 1990), *Actinomyces graevenitzii* (Pascual Ramos et al., 1997a), *Actinomyces hordeovulneris* (Buchanan et al., 1984), *Actinomyces hyovaginalis* (Collins et al., 1993), *Actinomyces marimammalium* (Hoyles et al., 2001c), *Actinomyces meyeri* (Cato et al., 1984), *Actinomyces naeslundii sensu stricto* (Howell et al., 1959), *Actinomyces nasicola* (Hall et al., 2003d), *Actinomyces neuii* (Funke et al., 1994), *Actinomyces odontolyticus* (Schaal, 1986b), *Actinomyces oricola* (Hall et al., 2003c), *Actinomyces. oris* and *Actinomyces johnsonii* (Johnson et al., 1990), *Actinomyces radicidentis* (Collins et al., 2000), *Actinomyces radingae* and *Actinomyces turicensis* (Wüst et al., 1995a), *Actinomyces slackii* (Dent and Williams, 1986), *Actinomyces suimastitidis* (Hoyles et al., 2001a), *Actinomyces urogenitalis* (Nikolaitchouk et al., 2000), *Actinomyces vaccimaxillae* (Hall et al., 2003a), and *Actinomyces viscosus sensu stricto* (Howell, 1963; Howell et al., 1965) are all able to grow in air on the surface of suitable agar media, although growth of some species (e.g., *Actinomyces viscosus sensu stricto*) may be very weak or they may even fail to grow when no CO_2 is available in the medium or the incubation atmosphere. In liquid media, aerobic growth may be better, provided that a large inoculum is used. However, aerobic growth yields are usually greatly increased when the atmosphere contains carbon dioxide (approx. 5%) or when HCO_3^- is added to the medium. *Actinomyces massiliensis* and most strains of *Actinomyces viscosus sensu stricto* appear to obligately require 5% CO_2 for growth and do not grow at all in air without added CO_2 (Howell, 1963; Renvoise et al., 2009). The aerotolerant *Actinomyces* species with an obligate or facultative requirement of CO_2 may be described most appropriately as capnophilic.

While some of the species mentioned above grow equally well in air, usually with added CO_2, and under anaerobic conditions (e.g., *Actinomyces denticolens*, *Actinomyces hyovaginalis*, *Actinomyces massiliensis*, *Actinomyces radicidentis*, *Actinomyces radingae*, *Actinomyces slackii*, and *Actinomyces turicensis*), others definitely prefer anaerobic growth conditions and produce weaker or even very weak growth when incubated in air with added CO_2 (e.g., *Actinomyces bovis*, *Actinomyces cardiffensis*, *Actinomyces georgiae*, *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces meyeri*, *Actinomyces nasicola*, *Actinomyces oricola*, and *Actinomyces vaccimaxillae*) (Cato et al., 1984; Hall et al., 2002, 2003a, 2003c, 2003d; Johnson et al., 1990; Schaal, 1986b). As reported by Pascual et al. (1999), growth of *Actinomyces bowdenii* is not enhanced by increased concentrations of CO_2 between 1.5 and 10%. Only certain strains of *Actinomyces bovis*, *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces meyeri* and the recently described new *Actinomyces* species *Actinomyces dentalis* (Hall et al., 2005), *Actinomyces hongkongensis* (Woo et al., 2003), and *Actinomyces ruminicola* (An et al., 2006) may be considered or were described as strict anaerobes.

It has been known for decades that species such as *Actinomyces bovis*, *Actinomyces gerencseriae*, (*Actinomyces israelii* serovar II), *Actinomyces israelii*, and *Actinomyces meyeri* exhibit a marked strain variation as far as aerotolerance is concerned (Schaal, 1986b). Furthermore, consistently good anaerobic growth is usually only obtained with added CO_2 or HCO_3^- while under anaerobic conditions without CO_2 most strains will not grow at all or only produce poor growth (Howell and Pine, 1956; Schofield and Schaal, 1981). On the other hand, nearly all of the *Actinomyces* species, including the aerotolerant ones, will multiply well at low oxygen tension with added CO_2 so that the genus *Actinomyces* as a whole may be considered a taxon of facultative anaerobes with obligate carbon dioxide requirement and variation in oxygen tolerance (Erikson, 1940; Howell, 1963; Schaal, 1986b; Slack and Gerencser, 1975). For these reasons, sophisticated anaerobic techniques such as the roll tube method or the anaerobic glove box are usually not required for the cultivation of these actinomycetes. It remains to be seen if this also holds true for the supposedly strictly anaerobic species *Actinomyces dentalis*, *Actinomyces hongkongensis*, and *Actinomyces ruminicola*.

The optimum growth temperature of most of the *Actinomyces* species validly published so far is 30–37°C (Schaal et al., 2006; Slack, 1974; Slack and Gerencser, 1975). Detailed studies on the temperature requirements of these organisms have rarely been performed. Most strains of *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato* were reported to produce also visible growth at lower temperatures ranging from 28 to 32°C (Howell, 1963), Schaal, unpublished results; Thompson and Lovestedt, 1951). Growth of hamster strains of *Actinomyces viscosus* (*Actinomyces viscosus sensu stricto*) even occurred at 23°C when the organism was incubated in air with added CO_2 or in an atmosphere of CO_2 and N_2 on BHIA (Howell, 1963). *Actinomyces naeslundii sensu*

lato and *Actinomyces viscosus sensu lato* may also grow at 45°C (Holmberg and Nord, 1975). *Actinomyces meyeri* strains were reported to grow equally well at 30 and 37°C and nearly as well at 25°C. No growth was obtained at 45°C (Cato et al., 1984). *Actinomyces massiliensis* produced good growth at 37°C and weak growth at 30°C, but no growth was observed at 25°C or 44°C, respectively (Renvoise et al., 2009). *Actinomyces ruminicola* is the only *Actinomyces* species described so far which differs greatly in growth temperature (20–55°C, with optimum growth at 46°C; An et al., 2006).

Actinomyces species including most of the new members of the genus tested so far usually ferment glucose to formic, acetic, lactic, and succinic acids when grown anaerobically with added CO_2 (Buchanan and Pine, 1965; Holdeman et al., 1977; Howell and Pine, 1956; Schofield and Schaal, 1981). The amount of succinic acid formed depends on the concentration of CO_2/HCO_3^- available in the medium, but lactic and succinic acids are thought to be the most characteristic fermentation end products of *Actinomyces* species. Anaerobically without added CO_2, the fermentation of "*Actinomyces israelii*" ATCC 10049 which is now considered to belong to the species *Actinomyces gerencseriae* was described as being homolactic (Buchanan and Pine, 1965). In the presence of CO_2, however, the fermentation was heterolactic with formate, acetate, lactate, and succinate as end products. Carbon dioxide when present is utilized (Howell and Pine, 1956).

Metabolism and metabolic pathways. In a detailed study on the carbohydrate metabolism of *Actinomyces viscosus sensu lato* in continuous culture under glucose or nitrogen limitation (Hamilton and Ellwood, 1983), it was shown that the molar growth yields were lower under nitrogen limitation than under glucose limitation. This indicates that the presence of utilizable nitrogen sources may be equally important for the growth of this organism in the oral cavity as the presence of suitable carbohydrates.

Actinomyces meyeri only occasionally forms small amounts of lactic acid and may also produce small quantities of pyruvic acid (Cato et al., 1984). The latter acid was also detected together with lactate in culture supernatants of *Actinomyces georgiae* when the tubes were inoculated aerobically and then restoppered, but not when the cultures were inoculated under CO_2 (Johnson et al., 1990). Formic acid was reported to be the main end product of glucose fermentation by *Actinomyces ruminicola* in addition to smaller amounts of acetic and lactic acids (An et al., 2006).

Energy is produced by substrate phosphorylation, but the amount of ATP produced depends on the cultural conditions. The results of Buchanan and Pine (1967) indicate that 4 mol of ATP are formed per mol of glucose when "*Actinomyces israelii*" (= *Actinomyces gerencseriae*) is incubated aerobically with added CO_2. Anaerobically without CO_2, only 2 mol of ATP are produced.

Several *Actinomyces* enzymes involved in the initial dissimilation of exogenous carbohydrates or the energy yielding glycolytic pathway have been identified and some were characterized in more detail. α-Galactosidase activities were observed in *Actinomyces denticolens*, *Actinomyces israelii* and in about one half of the tested isolates of *Actinomyces johnsonii*, *Actinomyces naeslundii sensu stricto*, and *Actinomyces oris* (Henssge et al., 2009). β-Galactosidase was found in *Actinomyces denticolens*, *Actinomyces israelii*, *Actinomyces massiliensis*, *Actinomyces viscosus sensu lato*, and in the majority of the *Actinomyces johnsonii*, *Actinomyces naeslundii sensu stricto*, and *Actinomyces oris* isolates examined (Henssge et al., 2009; Renvoise et al., 2009; Schaal et al., 2006). *Actinomyces denticolens*, *Actinomyces israelii*, *Actinomyces johnsonii*, and *Actinomyces naeslundii sensu stricto* were found to dispose of α- and β-glucosidases and the former enzyme was also present in *Actinomyces massiliensis*, *Actinomyces meyeri*, and *Actinomyces viscosus sensu lato*, and the latter in *Actinomyces odontolyticus* and the majority of the *Actinomyces oris* isolates. *Actinomyces israelii*, presumably *Actinomyces gerencseriae* and a few *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* isolates showed β-xylosidase activities. *Actinomyces odontolyticus* strains were the only "classical" fermentative actinomycetes which contained α-fucosidase. α-Mannosidase was not detected in any of these actinomycetes (Dent and Williams, 1984b; Kilian, 1978; Paddick et al., 2005; Peros and Gibbons, 1981; Renvoise et al., 2009; Schofield and Schaal, 1981).

The β-galactosidase of *Actinomyces viscosus sensu lato* was reported to have a molecular mass of 4.2×10^5, a K_m for lactose of about 6 mM, and a pH optimum between 6.0 and 6.5 (Kiel et al., 1977). Invertase activity has been demonstrated in *Actinomyces naeslundii sensu lato* (Miller, 1974) and *Actinomyces viscosus sensu lato* (Kiel et al., 1977; Palenik and Miller, 1975). The characteristics of the *Actinomyces viscosus* invertase were a molecular mass of 8.6×10^4, a K_m for sucrose of about 71 mM, and a pH optimum between 5.8 and 6.3. The enzyme was noncompetitively inhibited by fructose 6-phosphate and fructose 1,6-diphosphate (Kiel and Tanzer, 1977).

Fructose-1,6-diphosphate aldolase and phosphate acetyltransferase activities were demonstrated in cell-free extracts of "*Actinomyces israelii*" (= *Actinomyces gerencseriae*) (Buchanan and Pine, 1967). A nicotinamide adenine dinucleotide-dependent lactate dehydrogenase of *Actinomyces viscosus sensu lato* purified by Brown et al. (1975) had a molecular mass of 1×10^5 and a pH optimum of 5.5–6.2 and was under negative control by adenosine 5′-triphosphate and inorganic phosphate. Malate and glutamate dehydrogenases were detected in extracts of *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato*, but differed in their electrophoretic mobilities (Fillery et al., 1978). 6-Phosphogluconate dehydrogenase was only demonstrated in *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato*, but not in *Actinomyces gerencseriae* and *Actinomyces israelii* (Fillery et al., 1978).

Certain *Actinomyces* species synthesize extracellular and cell-associated polymers such as levan, dextran, or glycogen which enable them to attach directly to tooth surfaces. Such polymers produced by *Actinomyces viscosus sensu stricto* and *sensu lato* have been studied in detail (Hamilton and Ellwood, 1983; Howell and Jordan, 1967; Imai and Kuramitsu, 1983; Komiyama et al., 1988; Warner and Miller, 1978). The levan produced by these organisms formed a capsule tenaciously adhering to the cells under certain conditions (Warner and Miller, 1978). The enzyme levansucrase which is responsible for the production of the high-molecular-weight polymers was found to occur both in the growth medium and associated to the cell wall (Pabst, 1977; Pabst et al., 1979). On the other hand, *Actinomyces viscosus sensu lato* have levan-hydrolyzing activity (Miller and Somers, 1978) due to an extracellular and cell-associated enzyme that degrades the levan of *Actinomyces viscosus* as well as inulin and other levans. Similar synthetic

and degrading capacities for such polymers were also observed in *Actinomyces naeslundii sensu lato* (Komiyama et al., 1988; Miller and Somers, 1978).

Most *Actinomyces* species do not exhibit any detectable proteolytic activity (Schofield and Schaal, 1981; Slack and Gerencser, 1975). *Actinomyces bovis*, *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces meyeri*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, *Actinomyces viscosus sensu lato*, and most of the recently described species do not liquefy gelatin or Loeffler's serum nor do they hydrolyze casein, peptonize milk, or digest meat (Holdeman et al., 1977; Schaal et al., 2006; Schofield and Schaal, 1981; Slack, 1974; Slack and Gerencser, 1975). However, 40–60% of the *Actinomyces georgiae* strains tested (Johnson et al., 1990) were reported to liquefy gelatin, and *Actinomyces radicidentis* and one strain of *Actinomyces radingae* were described as being weakly gelatin-positive (Collins et al., 2000; Vandamme et al., 1998). Litmus milk may be acidified, reduced and/or clotted by several *Actinomyces* species apparently due to their saccharolytic activities (Slack and Gerencser, 1975).

The ability to deaminate or decarboxylate amino acids is also uncommon in the genus *Actinomyces* (Schaal, 1986b). Nevertheless, most strains of *Actinomyces israelii* and a few *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* strains are capable of producing ammonia from arginine. Furthermore, some *Actinomyces odontolyticus* strains may decarboxylate lysine (Schofield and Schaal, 1980, 1981). *Actinomyces bovis*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, and *Actinomyces viscosus sensu lato* may form hydrogen sulfide when grown on triple-sugar iron agar (TSIA), although they do not blacken the indicator in the medium, but only lead acetate paper strips suspended over the medium. Similarly, certain strains of *Actinomyces bovis*, *Actinomyces naeslundii sensu lato*, and *Actinomyces odontolyticus* were reported to show H_2S production over BHIA (Slack and Gerencser, 1975). Indole is not produced by any member of the genus *Actinomyces* (Henssge et al., 2009; Schaal et al., 2006).

With the exception of some strains of *Actinomyces johnsonii*, *Actinomyces meyeri*, *Actinomyces naeslundii*, *Actinomyces oris*, and *Actinomyces radicidentis*, all other *Actinomyces* species tested so far are urease-negative (Collins et al., 2000; Henssge et al., 2009; Schaal, 1986b; Schaal et al., 2006; Schofield and Schaal, 1981).

Adenine, guanine, hypoxanthine, tyrosine, and xanthine are not hydrolyzed (Schofield and Schaal, 1981). Hippurate hydrolysis is rare among members of the genus *Actinomyces* and was thus far only reported for *Actinomyces funkei* (Lawson et al., 2001b) and the "vaginal" biovar of *Actinomyces hyovaginalis* (Collins et al., 1993).

Esculin hydrolysis was previously thought to be very common among *Actinomyces* species (Schaal, 1986b; Schofield and Schaal, 1981; Slack and Gerencser, 1975) although strain variation had been noted. The latter particularly applies to the species *Actinomyces bovis*, *Actinomyces europaeus*, *Actinomyces georgiae*, *Actinomyces odontolyticus*, and *Actinomyces ruminicola* which encompass both esculin-positive and -negative strains. *Actinomyces meyeri*, *Actinomyces radingae*, and *Actinomyces turicensis* strains are, apart from a few exceptions, esculin-negative. Completely negative are, however, members of the new *Actinomyces* species *Actinomyces canis*, *Actinomyces cardiffensis*, *Actinomyces coleocanis*, *Actinomyces funkei*, *Actinomyces graevenitzii*, *Actinomyces hongkongensis*, *Actinomyces marimammalium*, *Actinomyces nasicola*, *Actinomyces neuii*, and *Actinomyces slackii* (Schaal et al., 2006).

Starch hydrolysis is a consistent feature of *Actinomyces bovis* and possibly *Actinomyces viscosus sensu stricto* (Howell and Jordan, 1963) although exceptions occur. It may also be found in some strains of a few other *Actinomyces* species such as *Actinomyces georgiae* or *Actinomyces johnsonii* (Johnson et al., 1990; Schaal et al., 2006; Schofield and Schaal, 1981; Slack and Gerencser, 1975). Hydrolysis of Tweens is weak or absent; lipase as observed on egg yolk-containing agar media or using the API system has not been detected (Schaal et al., 2006; Schofield and Schaal, 1981).

Lecithinase activity has only been found in a few *Actinomyces israelii sensu lato* isolates (Schofield and Schaal, 1981). The Voges–Proskauer reaction is usually negative (Holmberg and Nord, 1975; Howell and Jordan, 1963; Slack and Gerencser, 1975); weakly positive test results were reported for *Actinomyces suimastitidis* (Hoyles et al., 2001a) and *Actinomyces radicidentis* (Collins et al., 2000). Acetoin production of *Actinomyces urogenitalis* was found to be variable (Nikolaitchouk et al., 2000). The methyl red test is usually positive (Holmberg and Nord, 1975; Slack and Gerencser, 1975). No chondroitin sulfatase activity has been detected and hyaluronidase has only been found in a few *Actinomyces odontolyticus* strains. DNase is absent in *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces meyeri*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato*, but present in *Actinomyces bovis* and some strains of *Actinomyces odontolyticus* (Schofield and Schaal, 1981).

Using API test kits (API-BioMérieux), a large variety of further enzymic activities can be observed: All of the *Actinomyces* species tested previously were found to be negative for α-arabinosidase, β-mannosidase, β-glucuronidase (except for *Actinomyces catuli*), lipase C14, chymotrypsin, and trypsin (Kilian, 1978; Schaal et al., 2006; Schofield and Schaal, 1981). However, Renvoise et al. (2009) reported that single strains (the type strains) of *Actinomyces gerencseriae*, *Actinomyces israelii*, and *Actinomyces catuli* were α-arabinosidase-positive. Henssge et al. (2009) claimed that 88% of *Actinomyces naeslundii sensu stricto*, 93% of *Actinomyces oris*, and 100% of *Actinomyces johnsonii* strains tested were α-arabinosidase-positive when using a method other than the API Rapid ID32A kit. Essentially all of the other substrates included in the API enzyme test system give results that can be used for identification purposes because they exhibit characteristic species differences (Schaal et al., 2006) (Table 4, Table 5, Table 7, and Table 9). Leucine arylamidase activity is present in all members of the genus except *Actinomyces radingae* which was reported to be consistently negative in this trait (Vandamme et al., 1998). Phosphoamidase activity appears to be a typical characteristic of *Actinomyces denticolens*, but may also be found in certain strains of *Actinomyces gerencseriae*, *Actinomyces israelii*, and *Actinomyces odontolyticus*. Phospholipase A activity has not been detected in the "classical" *Actinomyces* species tested (Bulkacz et al., 1979).

The absence of catalase was once thought to be a characteristic of all *Actinomyces* species except *Actinomyces viscosus* (Schofield and Schaal, 1981; Slack, 1974; Slack and Gerencser, 1975).

However, with the description of many new members of the genus, the number of catalase-positive species has increased considerably. In addition to *Actinomyces viscosus sensu stricto*, *Actinomyces bowdenii*, *Actinomyces canis*, *Actinomyces hordeovulneris*,

Actinomyces neuii, *Actinomyces radicidentis*, and *Actinomyces slackii* have been shown to possess this enzyme. Catalase activity can also be observed in about half of the *Actinomyces oris* isolates and in very few strains of *Actinomyces naeslundii sensu stricto*. As far as *Actinomyces johnsonii* is concerned, conflicting results have been reported in the literature (Henssge et al., 2009; Johnson et al., 1990). Catalase activity is usually weak to moderate in *Actinomyces hordeovulneris* (Buchanan et al., 1984) and is present in *Actinomyces catuli* isolates (Hoyles et al., 2001b).

Cytochrome oxidase activity has been reported for some strains of *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* (Schofield and Schaal, 1981). However, the results of the benzidine test used for the detection of cytochrome oxidase do not necessarily correspond with the detection of cytochromes in cell extracts of actinomycetes by low temperature spectrophotometry (Taptykova and Kalakoutskii, 1973). *Actinomyces bovis*, *Actinomyces israelii*, *Actinomyces viscosus sensu lato*, and *Arcanobacterium pyogenes* apparently all contain cytochrome *b* (Reddy et al., 1977; Taptykova and Kalakoutskii, 1973). It was assumed that in *Arcanobacterium pyogenes*, cytochrome *b* mediates the reduction of fumarate to succinate, with reduced nicotinamide adenine dinucleotide as the electron donor (Reddy et al., 1982). *Actinomyces viscosus sensu lato* may contain cytochromes *a* and *c* in addition to cytochrome *b* (Taptykova and Kalakoutskii, 1973).

Nearly all of the members of the species or subspecies of *Actinomyces bowdenii*, *Actinomyces catuli*, *Actinomyces denticolens*, the "vaginal" biovar of *Actinomyces hyovaginalis*, *Actinomyces israelii*, *Actinomyces johnsonii*, *Actinomyces massiliensis*, *Actinomyces naeslundii sensu stricto*, *Actinomyces neuii* subsp. *neuii*, *Actinomyces odontolyticus*, and *Actinomyces ruminicola* are able to reduce nitrate to nitrite (An et al., 2006; Henssge et al., 2009; Johnson et al., 1990; Renvoise et al., 2009; Schaal et al., 2006). Nitrate reduction is variable in *Actinomyces cardiffensis*, *Actinomyces funkei*, *Actinomyces oris*, *Actinomyces radicidentis*, and *Actinomyces viscosus sensu stricto*. It is rarely positive in *Actinomyces georgiae* and *Actinomyces gerencseriae*. *Actinomyces neuii* subsp. *anitratus* is *per definitionem* nitrate reductase-negative (Funke et al., 1994) and the remaining *Actinomyces* species known so far are also unable to reduce nitrate (Hall et al., 2005; Johnson et al., 1990; Schaal et al., 2006; Schofield and Schaal, 1981; Slack, 1974; Slack and Gerencser, 1975). The ability to reduce nitrite appears to be uncommon in the genus, but may be seen in many *Actinomyces naeslundii sensu lato* strains (Schofield and Schaal, 1980; Schofield and Schaal, 1981) although this feature may often be difficult to detect (Dent and Williams, 1984b).

Some *Actinomyces* species exhibit β-hemolytic activities which may vary depending on the erythrocytes used (Slack, 1974). *Actinomyces bovis* usually shows β-hemolysis on media containing human erythrocytes and may also lyse sheep and horse red blood cells. *Actinomyces odontolyticus* strains vary in their β-hemolytic activity irrespective of the erythrocytes used. However, *Actinomyces odontolyticus* isolates, some *Actinomyces bovis* and *Actinomyces meyeri* strains, about one half of *Actinomyces oris* isolates, the majority (78%) of *Actinomyces naeslundii sensu stricto* cultures, and a few *Actinomyces viscosus sensu stricto* isolates may produce an area of greening around the colonies (α-hemolysis) when grown on human, sheep, or rabbit blood agar (Johnson et al., 1990; Schofield and Schaal, 1981; Slack, 1974). A few *Actinomyces hordeovulneris* isolates were reported to exhibit a weak hemolytic activity on bovine blood agar while most strains of this species were non-hemolytic (Buchanan et al., 1984).

Most of the remaining *Actinomyces* species are non-hemolytic or their hemolytic properties have not been reported. Weak hemolysis was observed in strains of *Actinomyces radingae*, which appeared slowly and started mostly as α-hemolysis, and in *Actinomyces turicensis*, especially when incubated with added CO_2 or anaerobically (Vandamme et al., 1998). Most strains of *Actinomyces neuii* subsp. *neuii* exhibit α-hemolysis on sheep blood agar as do all strains on human blood agar. *Actinomyces neuii* subsp. *anitratus* is non-hemolytic (Funke et al., 1994).

Adherence mechanisms. Certain *Actinomyces* species, in particular *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato*, have been shown to possess mechanisms which enable them to adhere to hard and smooth surfaces and epithelial cells, to coaggregate with each other or with other bacteria, or to agglutinate red blood cells. Further studies revealed that obviously more than one mechanism is involved in these adherence and coaggregation functions. The simplest of these attachment mechanisms is the production of extracellular or cell-associated polymers (glycocalyx), especially dextran, levan, glycogen, and *N*-acetylglucosamine-rich slime polysaccharides, which make the cells sticky so that they become able to attach to enamel, artificial denture materials and even glass. *Actinomyces viscosus sensu stricto* (Howell and Jordan, 1963, 1967) and *Actinomyces viscosus* serovar II strains (*Actinomyces oris*) (Bourgeau and McBride, 1976; Hamilton and Ellwood, 1983; Imai and Kuramitsu, 1983; Miller et al., 1978; Ooshima and Kuramitsu, 1985; Pabst, 1977), as well as *Actinomyces naeslundii sensu lato* (Komiyama et al., 1988; Slack and Gerencser, 1975), have been shown to produce these polymers.

Enhancement of aggregation by low pH values indicated that alterations of the cell surface potential might be involved in the aggregation process (Miller et al., 1978). Most importantly, however, the so-called surface fibrils or fimbriae that are produced by several *Actinomyces* species were found to mediate both interbacterial aggregation and adhesion processes of fermentative actinomycetes. The fimbriae of *Actinomyces viscosus* T14V consist of high molecular mass proteins with some carbohydrate and up to 14.3% nitrogen (Cisar and Vatter, 1979; Masuda et al., 1983). That such fimbrial proteins might be responsible for attachment and coaggregation, was first suggested by the finding that treatment with proteolytic enzymes or heat could impair the coaggregation between *Actinomyces naeslundii sensu lato* or *Actinomyces viscosus sensu lato* on the one hand and *Streptococcus sanguinis* and *Streptococcus mitis* on the other hand (Ellen and Balcerzak-Raczkowski, 1977; McIntire et al., 1978).

It soon became apparent that a lectin-like mechanism was involved in some of these interbacterial coaggregations. McIntire et al. (1978) found that the coaggregation between *Actinomyces viscosus* T14V and *Streptococcus sanguinis* 34 required a protein or glycoprotein on *Actinomyces viscosus* and a carbohydrate on *Streptococcus sanguinis*. This coaggregation as well as the binding of *Actinomyces viscosus* to glycoprotein-coated latex beads and its hemagglutinating properties were specifically inhibited by lactose, β-methyl-D-galactoside, and D-galactose, but not or only weakly inhibited by α-methyl-D-galactoside, melibiose, maltose, cellobiose, sucrose, and a number of monosaccharides (Costello et al., 1979; Heeb et al., 1985). Costello et al. (1979)

and Ellen et al. (1980) reported that *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* were able to agglutinate human AB and horse erythrocytes. This agglutinating property was enhanced by pretreatment of the red blood cells with neuraminidase and specifically inhibited by the compounds mentioned before. Furthermore, it was suggested that the actinomycetes could prime erythrocytes and human buccal epithelial cells for hemagglutination or attachment by removing sialic acid to expose more penultimate β-galactosides on the surface of the cells. Thus, neuraminidase removal of terminal sialic acid and lectin-like binding to exposed β-galactoside-associated sites on the erythrocytes appeared to be responsible for the hemagglutination and adherence capabilities of *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* (Saunders and Miller, 1983). Lectin-dependent attachment of *Actinomyces naeslundii sensu lato* to human epithelial cells could clearly be related to the lactose-sensitive fimbriae (type 2 fimbriae) of strain WVU 45 (Brennan et al., 1984). Further characterizing the epithelial cell receptor for the bacterial lectin, Brennan et al. (1984) showed that plant lectins from *Bauhinia purpurea* and *Arachis hypogaea* had specificities similar to that of the *Actinomyces naeslundii* fimbrial lectin.

Numerous studies have demonstrated that the coadhesion mechanisms between oral microbes are complex. *Actinomyces viscosus* T14V was shown to possess a highly specific aggregation factor for *Streptococcus sanguinis* H1 (AFH1) which mediated coadhesion that was not inhibited by lactose (Mizuno et al., 1983). The most active fraction of AFH1 reacted as a single antigen with anti-*Actinomyces viscosus* T14V serum and was unrelated to the fimbrial antigens of this organism. It was composed of approximately 53% cell-wall components, 40% polysaccharide, and 7% protein, but did not contain teichoic acid. Thus, it was concluded that a carbohydrate-protein interaction might be dominant in the aggregation of *Streptococcus sanguinis* H1 by AFH1 and in the coaggregation of *Streptococcus sanguinis* H1 with *Actinomyces viscosus* T14V.

In the coaggregation between *Capnocytophaga gingivalis* DR2001 and *Actinomyces israelii* PK16, an adhesin on *Capnocytophaga gingivalis* was identified that mediates the interaction (Tempro et al., 1989). This adhesin was a 140-kDa polypeptide located in the outer membrane of *Capnocytophaga gingivalis* whose molecules were arranged non-uniformly on the bacterial surface, occurred singly, in pairs, and in small clusters, and reacted with carbohydrate receptors on *Actinomyces israelii*. In contrast, fimbriae of *Porphyromonas gingivalis* were found to mediate the coadhesion of this organism with *Actinomyces viscosus sensu lato* (Goulbourne and Ellen, 1991). Similarly, fimbriae-associated proteins of *Prevotella (Bacteroides) loescheii* were found to induce coaggregation with *Streptococcus sanguinis* 34 and *Actinomyces israelii* PK14 (Weiss et al., 1987). However, while coadhesion with *Streptococcus sanguinis* was inhibited by lactose, that with *Actinomyces israelii* was not.

Denaturing polyacrylamide gel electrophoresis and immunoblot analysis revealed the presence of both a 75- and a 43-kDa protein associated with parental fimbriae, the former protein being responsible for the recognition of *Streptococcus sanguinis* and the latter for that of *Actinomyces israelii*. Studying the coaggregation of *Prevotella intermedia* with oral *Actinomyces* species, Nesbitt et al. (1993) found that a protein or glycoprotein located on *Prevotella intermedia* strain 27 interacted with carbohydrate-containing molecules on the surface of *Actinomyces viscosus* T14V, *Actinomyces naeslundii* ATCC 12104, and additional *Actinomyces naeslundii sensu lato* strains. Comparing these coaggregations with those between *Prevotella intermedia* 113 and *Actinomyces odontolyticus* WVU 1546 or *Actinomyces israelii* WVU 838, it was suggested that different surface molecules of *Prevotella intermedia* 113 mediated each of the latter coaggregations.

More detailed studies have shown that *Actinomyces viscosus sensu lato* possesses two types of fimbriae: type 1 fimbriae are involved in the attachment of this organism to saliva-coated hydroxyapatite whereas type 2 fimbriae mediate the lectin-dependent coaggregation with *Streptococcus sanguinis* that can be inhibited by lactose (Cisar et al., 1984a, 1984b, 1988; Clark et al., 1986; Mergenhagen et al., 1987). Using specific polyclonal and monoclonal antibodies, Ellen et al. (1989) demonstrated that anti-type 2 antibodies bound to antigens on long fibrils whereas anti-type 1 antibodies were mostly localized close to the cell body or on short appendages.

Typical human isolates of *Actinomyces naeslundii*, which possibly represent members of *Actinomyces naeslundii sensu stricto*, were reported to elaborate a single fimbriae type, namely type 2 fimbriae. Thus, the two genospecies of *Actinomyces naeslundii*, defined by Johnson et al. (1990) (*Actinomyces naeslundii sensu stricto* and *Actinomyces oris*), apparently differ with respect to the fimbriae expressed: Type 1 fimbriae are mainly present on *Actinomyces oris* while type 2 fimbriae are expressed by both *Actinomyces naeslundii sensu stricto* and *Actinomyces oris* (Cisar et al., 1984b; Strömberg et al., 1996).

The specificity of the lectins present on the fimbriae of certain *Actinomyces naeslundii* strains was found to be similar to but not identical with that of certain *Actinomyces viscosus* lectins (Cisar et al., 1984a, 1984b; McIntire et al., 1983). These lectins mediate binding to β-1,3-linked galactose or galactosamine structures in cell surface glycolipids and glycoproteins (Brennan et al., 1984; McIntire et al., 1983; Strömberg and Boren, 1992; Strömberg and Karlsson, 1990), salivary glycoproteins (Strömberg et al., 1992), and streptococcal capsular polysaccharides (Abeygunawardana et al., 1991). However, *Actinomyces naeslundii sensu stricto* ATCC 12104 and *Actinomyces oris* LY7 showed different binding patterns to a panel of saccharides containing β-linked galactose or galactosamine structures (Strömberg et al., 1996; Strömberg and Boren, 1992).

A 57-kDa protein from *Actinomyces viscosus* WVA 963 (*Actinomyces johnsonii*) was implicated as the type 2 fimbrial subunit while a 95-kDa protein appeared to be a putative *Actinomyces* adhesin mediating the lactose-inhibitable coaggregation with streptococci (Klier et al., 1997). Further studies with a coaggregation-defective mutant of this *Actinomyces johnsonii* strain confirmed the role of the 95-kDa protein which, in its secreted form, was bound to streptococcal partner cells and to lactose-agarose affinity beads (Klier et al., 1998).

In contrast, type 1 fimbriae mediate attachment to saliva-treated surfaces (Clark et al., 1984, 1986). Gibbons and coworkers (Gibbons, 1989; Gibbons and Hay, 1988; Gibbons et al., 1988) have implicated acidic proline-rich proteins (APRPs) and statherin derived from human parotid or submandibular saliva as promoting the attachment of *Actinomyces viscosus* (*Actinomyces oris*) to apatitic surfaces. *In vitro* studies with PRP- or PRG (proline-rich glycoproteins)-coated polystyrene or hydroxyapatite surfaces confirmed and extended these observations

(Clark et al., 1989). Subsequent findings using mutant strains of *Actinomyces viscosus sensu lato* indicated that a particular adhesive molecule probably associated with type 1 fimbriae allows for the interaction of *Actinomyces viscosus sensu lato* with constituents of the salivary pellicle (Nesbitt et al., 1992).

Analyzing the binding specificities of *Actinomyces naeslundii* genospecies 1 and 2 (*Actinomyces naeslundii sensu stricto* and *Actinomyces oris*, respectively) in detail, Hallberg et al. (1998a) found that *Actinomyces oris* commonly bound to *N*-acetyl-β-D-galactosamine and acidic proline-rich proteins. The *N*-acetyl-β-D-galactosamine binding specificity was signified by *N*-acetyl-β-D-galactosamine-inhibitable coaggregation with four specific streptococcal strains. Isolates of *Actinomyces naeslundii sensu stricto* also bound commonly to *N*-acetyl-β-D-galactosamine but less commonly to acidic proline-rich proteins. All of these isolates possessed another *N*-acetyl-β-D-galactosamine specificity in that they differed in their binding specificities when the same set of streptococcal strains was used.

In studies of coaggregation between *Streptococcus gordonii* and *Actinomyces naeslundii sensu lato*, six coaggregation groups of *Actinomyces naeslundii* were defined. These differed by heat and protease sensitivity and by the ability of spontaneous mutants to coaggregate with members of various groups of partner strains (Kolenbrander, 1989). The *Streptococcus gordonii* surface proteins SspA and SspB were found to be primarily responsible for defining these coaggregation groups (Egland et al., 2001) whose interaction modes are either inhibitable or unaffected in the presence of lactose (Kolenbrander, 1988; Kolenbrander and Williams, 1981). More recently, it was demonstrated (Hallberg et al., 1998b) that *Actinomyces naeslundii sensu lato* exhibits variant fimbrial subunit genes *fimP* (type 1) and *fimA* (type 2) which correspond to diverse APRP and Gal-*N*Acβ specificities, respectively, while *Actinomyces odontolyticus* was found to have genetically related but distinct adhesion binding specificity.

16S rRNA gene sequence and other molecular data. It has long been recognized that the genus *Actinomyces* exhibits considerable phenotypic diversity (Schaal, 1986b, 1992a; Schofield and Schaal, 1981). The dramatic increase in the number of *Actinomyces* species and the corresponding availability of nearly complete 16S rRNA gene sequence data of these species have allowed the construction of phylogenetic trees, which became more and more complex. Trees differed greatly from one another depending on the size of databases, the selection of strains and outgroups, and the treeing algorithms (Schaal et al., 2006). Nevertheless, all of these surveys confirmed that the genus *Actinomyces* is not only heterogeneous phenotypically, but shows pronounced phylogenetic diversity as well (Lawson et al., 1997; Pascual Ramos et al., 1997b; Schaal et al., 2006). Recent 16S rRNA gene sequence similarity analyses demonstrated unanimously that *Actinomyces* species form several phylogenetic clusters whose number depends on the cut-off branching points (Figure 19). However, the decision on what level these clusters should be considered taxonomically coherent entities apparently requires further chemotaxonomic, physiological, and morphological investigations (Schaal et al., 1999, 2006).

According to these phylogenetic analyses, *Actinomyces* species can be subdivided into two major (core clusters 1 and 2) and at least four minor phylogenetic clusters (Schaal et al., 2006) (Figure 19). Core cluster 1 is supported by high statistical significance (100% bootstrap value) and contains 15 or 17 species depending on whether *Actinomyces graevenitzii* and *Actinomyces radicidentis* are included or are considered individual lineages. The latter view was based on phylogenetic dendrograms published earlier (see Schaal et al., 2006) and, as far as *Actinomyces graevenitzii* is concerned, was supported by deviations in its set of signature nucleotides (see Table 1) while the 16S rRNA gene signature nucleotides of *Actinomyces radicidentis* suggested its inclusion in core cluster 1. The topical dendrogram shown in Figure 19 is of no additional help concerning the phylogeny of these species.

Actinomyces bovis, the type species of the genus *Actinomyces*, is a member of core cluster 1 as are the “classical” species *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato*. As strains of *Actinomyces naeslundii sensu stricto* and of *Actinomyces oris* exhibit >99% 16S rRNA gene sequence similarity between one another, and *Actinomyces johnsonii* strains exhibit >98.5% similarity with the two former species, these organisms cannot be reliably identified by 16S rRNA gene sequence comparison. The new species *Actinomyces johnsonii* and *Actinomyces oris* were, therefore, not included in the phylogenetic dendrogram which still contains *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato*. However, *Actinomyces oris* and *Actinomyces johnsonii* can apparently be identified and differentiated from *Actinomyces naeslundii sensu stricto* and *Actinomyces viscosus sensu stricto* by comparison of partial sequences of the housekeeping genes *atpA* and *metG* (Henssge et al., 2009). In addition, core cluster 1 comprises the recently described species *Actinomyces dentalis*, *Actinomyces denticolens*, *Actinomyces massiliensis*, *Actinomyces oricola*, and *Actinomyces ruminicola*, together with *Actinomyces bowdenii*, *Actinomyces catuli*, *Actinomyces howellii*, *Actinomyces slackii*, and *Actinomyces urogenitalis*, the latter species having been described between 1984 and 2001. The pattern of 16S rRNA signatures of core cluster 1 consists of nucleotides at positions 146:176 (U–G), 591:648 (G–Y), 614:626 (C–G), and 1311:1326 (U–A).

Members of core cluster 1, sharing 94–99% sequence similarity, may be considered authentic *Actinomyces* species as the cluster contains the type species *Actinomyces bovis* (Schaal et al., 2006). This species is closely related to *Actinomyces urogenitalis* as had already been pointed out in the original description of the latter species (Nikolaitchouk et al., 2000). Additional pairs of phylogenetic neighbors are *Actinomyces israelii* and *Actinomyces gerencseriae*, *Actinomyces slackii* and *Actinomyces bowdenii*, and *Actinomyces naeslundii sensu stricto* and *Actinomyces viscosus sensu stricto*. All other species form individual lines of descent. Results of DNA–DNA reassociation studies (Dent and Williams, 1984a; Johnson et al., 1990) indicated that *Actinomyces denticolens*, *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii*, and *Actinomyces viscosus* form genomically well separated species. *Actinomyces gerencseriae* ATCC 23860^{T}, formerly considered a representative of *Actinomyces israelii* serovar II, was identified as a taxon distinct from *Actinomyces israelii* serovar I strains by oligonucleotide probing (Stackebrandt and Charfreitag, 1990) and low DNA reassociation values with DNA of *Actinomyces israelii sensu stricto* (Johnson et al., 1990).

Actinomyces graevenitzii, sharing less than 94% 16S rRNA gene sequence similarity with other members of the genus *Actinomyces* (Pascual Ramos et al., 1997a), appears to occupy a separate phylogenetic position as has been verified in subsequent

descriptions of new *Actinomyces* species (Hoyles et al., 2001a; 2001b; 2001c; 2002b; Nikolaitchouk et al., 2000; Pascual et al., 1999). The 16S rRNA gene sequence of the type strain of *Actinomyces graevenitzii* (CCUG 27294^T) contained several undetermined nucleotides, and erroneous stretches and deletions. The corrected sequence (Yassin unpublished) neither changed the similarity values nor the branching point but supported the distinct position of the organism. The pattern of 16S rRNA signatures of *Actinomyces graevenitzii* consists of nucleotides at positions 146:176 (U–G), 450:483 (C–G), 591:648 (G–Y), 614:626 (C–G), 835:851 (A–U), 668:738 (U–A), 669:737 (A–U), 1308:1329 (U–A), 1311:1326 (U–A), and 1308:1329 (U–G). However, the dendrogram depicted in the description of *Actinomyces radicidentis* (Collins et al., 2000) indicated that the latter species is only loosely attached to core cluster 1 so that both *Actinomyces graevenitzii* and *Actinomyces radicidentis* may represent distinct phylogenetic entities although this is not as obvious in the dendrogram shown in Figure 19.

Except for *Actinomyces odontolyticus*, *Actinomyces meyeri*, and *Actinomyces georgiae* which were described in 1958, 1984, and 1990, respectively, the second major cluster, core cluster 2 (86% bootstrap value) only contains species that have been described within the past 15 years, namely *Actinomyces canis*, *Actinomyces cardiffensis*, *Actinomyces funkei*, *Actinomyces hyovaginalis*, *Actinomyces radingae*, *Actinomyces suimastitidis*, *Actinomyces turicensis*, and *Actinomyces vaccimaxillae*. This means that core cluster 2 encompasses 11 species. The two biovars of *Actinomyces hyovaginalis* display a high 16S rRNA gene sequence similarity (98.8%) so that they cannot be clearly separated by this trait (Storms et al., 2002). They also show very similar DNA fingerprints of the amplified spacer regions in between the tRNA-genes and high DNA–DNA hybridization values (Storms et al., 2002). The pattern of 16S rRNA signatures of core cluster 2 consists of nucleotides at positions 154:167 (G–U), 316:337 (U–G), 591:648 (G,u–V), and 614:626 (C–G). In general, it should be noted that the subdivision of the genus *Actinomyces* into these two major clusters does not correspond with the human or animal sources of these species, respectively.

Actinomyces georgiae, *Actinomyces meyeri*, and *Actinomyces odontolyticus* are phylogenetic neighbors that have been subjected to DNA–DNA reassociation studies (Johnson et al., 1990). Low hybridization values confirmed their separate species status. *Actinomyces radingae*, which appeared as a remote relative of cluster 2 in a previous phylogenetic analysis (Schaal et al., 2006), seems to be a true member of core cluster 2 in Figure 19 so that its position in this dendrogram is more similar to that shown by Pascual Ramos et al. (1997b). Its membership in core cluster 2 is also supported by the set of signature nucleotides (Table 1) which is similar to that of other members of this cluster.

Actinomyces coleocanis and *Actinomyces europaeus* share a remote relationship of 94.2% sequence similarity. The branching point of this lineage is not settled as seen by different affiliations of either one or both species in recently published dendrograms (Collins et al., 2000; Hoyles et al., 2000, 2001b, 2002b; Nikolaitchouk et al., 2000; Pascual et al., 1999; Schaal et al., 2006). The presence of unique 16S rRNA gene nucleotide signatures (Table 1) highlights the separate phylogenetic position of these two species which are only distantly related to core clusters 1 and 2. The pattern of their 16S rRNA signatures consists of nucleotides at positions 146:176 (U–A), 501:544 (U–A), 502:543 (A–U), 586:755 (U–A), 1243:1294 (R–U), and 1310:1327 (U–A).

Actinomyces marimammalium and *Actinomyces hongkongensis* branch deeply within the tree of species of the *Actinomycetaceae* and are only loosely affiliated with core cluster 2 in the dendrogram shown in Figure 19. The bootstrap value for the two type strains is low. The signature nucleotides (Table 1) of *Actinomyces marimammalium* support its isolated phylogenetic position. This pattern of 16S rRNA signatures consists of nucleotides at positions 153:168 (G–U), 590:649 (G–U), 613:627 (A–U), and 1311:1326 (U–A).

An additional pair of outgroup species loosely affiliated with core cluster *2* is represented by *Actinomyces hordeovulneris* and *Actinomyces nasicola*. The phylogenetic position of *Actinomyces hordeovulneris* was not determined in the original description of this species (Buchanan et al., 1984), but was determined in the phylogenetic analysis of the genus *Actinomyces* published by Pascual Ramos et al. (1997b). An isolated phylogenetic position of *Actinomyces hordeovulneris* has been demonstrated since then in many subsequent studies (Schaal et al., 2006). Several deviations in the set of 16S rRNA gene sequence signatures from those of members of core cluster 2 support the phylogenetic relevance of these findings. The pattern of 16S rRNA signatures of this species consists of nucleotides at positions 154:167 (G–U), 839:847 (A–U), and 1308:1329 (U–A). The species *Actinomyces nasicola* has recently been added to this lineage.

Actinomyces neuii was described (Funke et al., 1994) before the phylogenetic diversity of the genus *Actinomyces* had been recognized. However, the separate position of this species, apart from other members of the genus, became apparent in several subsequent studies, but lack of distinct and differentiating phenotypic properties has hindered the formal description of a new genus for the former CDC group 1 (subspecies *neuii*) and CDC group 1-like coryneform bacteria (subspecies *anitratus*). The two groups were considered subspecies because of phenotypic differences observed for the phylogenetically highly related type strains (99.7% sequence similarity). Nonquantitative DNA hybridization (Funke et al., 1993), however, showed a low degree of overall genomic relatedness between members of the two subspecies. The pattern of 16S rRNA signatures of *Actinomyces neuii* consists of nucleotides at positions 153:168 (G–U), 378:385 (A–U), 407:435 (G–C), 450:483 (A–U), 601:637 (A–U), 602:636 (G–U), 668:738 (U–A), 669:737 (A–U), 1243:1294 (U–A), 1245:1292 (U–G), 1246:1291 (C–G), and 1310:1327 (C–G). The branching of *Varibaculum cambriense* adjacent to the *Actinomyces neuii* lineage is obviously without statistical significance.

Besides the 16S rRNA gene and certain housekeeping genes of the *Actinomyces naeslundii/Actinomyces viscosus* complex whose sequences were chiefly used for taxonomic purposes, several other genes have been sequenced and functionally characterized; these genes are or may be involved in the pathogenicity of the respective actinomycetes. For example, Yeung et al. (1998) determined the sequence of the *Actinomyces viscosus (Actinomyces oris?*) T14V type 2 fimbrial structural subunit gene, *fimA*, and the 3′ flanking DNA region. The *fimA* gene encoded a 535-amino-acid precursor subunit protein (FimA). A second

gene, *orf365*, that encoded a 365-amino-acid protein which contained a putative transmembrane segment was identified immediately 3′ to *fimA*. Deletion mutants of these genes did not participate in the type 2 fimbriae-mediated coaggregation with *Streptococcus oralis* 34. In addition, the nucleotide sequence of the chromosomal DNA flanking the *Actinomyces viscosus* T14V type 1 fimbrial structural subunit gene (*fimP*) was determined (Yeung and Ragsdale, 1997) in which six open reading frames were identified. These were further characterized in respect to their additional role in the synthesis and function of the fimbriae of *Actinomyces viscosus* T14V.

As the multisubunit enzyme urease may also be considered a virulence factor, the urease gene regulation and nitrogen metabolism of *Actinomyces naeslundii* WVU45 (=ATCC 12104 = *Actinomyces naeslundii sensu stricto*) was studied (Morou-Bermudez and Burne, 2000). In this study, it was demonstrated that urease activity and urease-specific mRNA levels in this strain can increase up to 50-fold during growth under nitrogen limitation. Using primer extension analysis, a putative, proximal, nitrogen-regulated promoter of the *Actinomyces naeslundii* urease gene cluster was identified whose functionality and nitrogen responsiveness were confirmed using reporter gene fusions and 5′ deletion analysis. From the data obtained, it was concluded that regulation of urease expression by nitrogen availability in *Actinomyces naeslundii* may require a positive transcriptional activator.

Mutants, plasmids, phages, and bacteriocins. Spontaneous mutants of certain *Actinomyces* species such as *Actinomyces viscosus sensu lato* or *Actinomyces naeslundii sensu lato* appear to occur comparatively frequently. The first of these mutant strains, T14AV, was characterized in some detail. It appeared spontaneously in a culture of *Actinomyces viscosus* T14V, a human oral strain which, according to the recent taxonomic revisions, belongs to the new species *Actinomyces oris* and it was used to study the periodontopathic potential of this species (Hammond et al., 1976). T14AV differed from the parent strain T14V as it proved to be non-virulent under certain experimental conditions. Upon further investigation, the morphological, chemical, and antigenic differences between the strains which could account for the impaired virulence of T14AV were shown to be quantitative rather than qualitative. For example, the virulent parent strain produced more fimbriae and more virulence-associated antigen than the mutant strain (Brecher et al., 1978; Cisar et al., 1978, 1980), a microcapsule was apparent on the mutant strain (Powell et al., 1978), and the mutant strain produced increased amounts of a viscous, extracellular polysaccharide (Brecher et al., 1978; Hammond et al., 1976). Due to these changes, the mutant strain T14AV displayed various adherence defects (Brecher et al., 1978; McIntire et al., 1978; Wheeler et al., 1979) and a decreased ability to colonize germ-free rats and to initiate periodontal pathology (Brecher et al., 1978; Hammond et al., 1976). Thus, the lower virulence of strain T14AV appeared to be related to several different factors and is probably not associated with a distinct structural change of the mutant cell surface.

Meanwhile, various other mutants were used to elucidate in detail adherence and pathogenicity mechanisms, particularly in relation to the development of caries and periodontal disease. For example, Cisar et al. (1983) described a spontaneous coaggregation-defective (COG$^-$) mutant, *Actinomyces viscosus* (*Actinomyces oris*) T14V(PK455), which associated the lectin activity with type 2 fimbriae, whereas strain T14AV provided little insight into the mechanisms of lactose-sensitive adherence. In addition, the precise nature of the cell surface modification displayed by strain T14V(PK455) provided clear evidence for the distinct and independent functions of type 1 and type 2 fimbriae of *Actinomyces viscosus* (*Actinomyces oris*) T14V.

Using rabbit antibodies against either or both fimbrial antigens, spontaneous mutants of *Actinomyces viscosus* (*Actinomyces oris*) T14V were isolated which lacked type 1, type 2, or both types of fimbriae (Cisar et al., 1988). These results allowed further insight into the function of both types of fimbriae, especially the ability of salivary acidic proline-rich proteins and statherin to serve as receptors for type 1 fimbriae. Mutagenesis with ethyl methanesulfonate of *Actinomyces viscosus* T14V-J1 and enrichment for cells non-reactive with proline-rich proteins (PRPs) by successive adsorption with PRP-treated latex beads resulted in mutants that exhibited reduced binding to hydroxyapatite coated with whole saliva or salivary protein preparations, but were still capable of reaction with antiserum to type 1 and type 2 fimbriae suggesting that an adhesive molecule was probably associated with type 1 fimbriae and allowed for the interaction of *Actinomyces viscosus* (*Actinomyces oris*) with constituents in the salivary pellicle (Nesbitt et al., 1992). Another coaggregation-defective mutant (*Actinomyces* serovar WVA 963, strain PK1259, which is now considered a member of the new species *Actinomyces johnsonii*) lacking type 2 fimbriae was shown to synthesize the putative adhesin, but appeared unable to present it properly on its surface (Klier et al., 1998).

The plasmid content of *Actinomyces* species appears to be very limited. Vandenbergh et al. (1982) were not able to detect plasmids in 17 strains of *Actinomyces viscosus sensu lato*, four strains of *Actinomyces odontolyticus*, and one strain of *Actinomyces israelii*. However, integration plasmids were used to generate site-specific mutations in the *Actinomyces viscosus* (*Actinomyces oris*) T14V chromosome (Yeung, 1995).

Although several groups of oral bacteria abundantly produce bacteriocins or bacteriocin-like activities, there is little evidence that *Actinomyces* species synthesize such substances. Holmberg and Hallander (1972) were unable to detect bacteriocin-like activities in strains of *Actinomyces viscosus sensu lato* and *Actinomyces naeslundii sensu lato*. Tompkins and Tagg (1986) observed inhibitory effects in 62 *Actinomyces* strains when incubated anaerobically, but little inhibitory activity was found under "microaerophilic" conditions and anaerobically in a medium buffered by 0.5% (w/v) calcium carbonate. It was therefore concluded that the inhibitory effect was due to the production of large amounts of lactic and succinic acids and the concomitant fall in the pH rather than to the production of bacteriocin-like substances. Turner and Jordan (1981) also reported that interstrain antagonism was low and, when present, induced only small and poorly defined inhibition zones. Only one report (Franker et al., 1977) suggests that a strain of *Actinomyces odontolyticus* isolated from dental plaque produced a non-dialyzable, trypsin-sensitive substance that was bactericidal for certain strains of bifidobacteria at 42°C but not at 37°C. However, treatment of the producer cells with curing agents did not induce a high frequency of non-bacteriocinogenic cells and the presumed bacteriocin was adsorbed by susceptible as well as resistant bacteria.

Information on bacteriophages of *Actinomyces* species is also rather scarce: Delisle et al. (1978) isolated a lytic phage from a sample of raw domestic sewage. This phage Av-1 produced clear plaques on a human isolate primarily identified as *Actinomyces viscosus* and was found to belong to Bradley's morphological group C (Bradley, 1967). It possessed a small polyhedral head measuring 40 nm in diameter and a short tail of 26 nm in length. At first, its host range appeared to be very narrow as it only infected one human isolate of *Actinomyces viscosus* (*Actinomyces oris*?) (strain MG-1), but it did not show lysis or growth inhibition when plated with 10 other *Actinomyces viscosus sensu lato* and 10 *Actinomyces naeslundii sensu lato* strains. Later, Delisle and Donkersloot (1995) showed this phage to be lytic for several human strains of *Actinomyces naeslundii sensu lato*. Recently, the lysis genes of Av-1 were isolated and characterized; the complete lysis region of Av-1 is comprised of two holin-like genes which were designated *holA* and *holB*, and an endolysin gene, designated *lysA* (Delisle et al., 2006).

When screening 336 human dental plaque samples for the presence of bacteriophage for *Actinomyces viscosus sensu lato*, 10 were found to contain virulent *Actinomyces* phages (Tylenda et al., 1985a). Again, a high host cell specificity of these phages was noted. One phage isolate only infected *Actinomyces viscosus* (*Actinomyces oris*) T14V, eight phage isolates infected only *Actinomyces viscosus* MG-1, and one infected both strains. One of the plaque samples yielding phage was examined for the presence of a natural host strain for that particular phage. Consequently, two actinomycetes strains identified as *Actinomyces viscosus* serovar II (*Actinomyces oris*) and *Actinomyces naeslundii* serovar I (*Actinomyces naeslundii sensu stricto*) were isolated.

Yeung and Kozelsky (1997) isolated bacteriophages from 22 of 124 samples of fresh human dental plaque. All *Actinomyces naeslundii sensu stricto*, *Actinomyces oris*, and *Actinomyces viscosus sensu stricto* strains tested were susceptible to infection with one or more of these phages. In contrast, none of the *Actinomyces odontolyticus*, *Actinomyces israelii*, or *Actinomyces bovis* isolates included in the study was sensitive. The genomes of these phages were found to consist of double-stranded DNA molecules 16–60 kbp in size. A temperate phage, designated Φ 225, produced a lysogenized strain of *Actinomyces viscosus* MG-1.

The use of such *Actinomyces* phages as tools for studying coaggregation between actinomycetes and streptococci revealed that the phages AV-1, AV-2, AV-3, and 1281 bound to coaggregation group A of *Actinomyces viscosus* and to group E of *Actinomyces naeslundii* (Tylenda et al., 1985b) but not to groups B, C, D, or F. Studies of another lytic *Actinomyces viscosus (Actinomyces oris)* T14V phage isolated from raw sewage and designated BF307 indicated that this phage recognizes a receptor on *Actinomyces viscosus* strains MG-1 and T14V that is related to one of the structures that mediates coaggregation with oral streptococci (Delisle et al., 1988). Hence such phages were thought to be useful for probing surface components of human oral actinomycetes.

Antigenic structure. Agglutination (Bellack and Jordan, 1972; Erikson, 1940; Holm, 1930; King and Meyer, 1957; Lentze, 1938a; Putnins and Bowden, 1993; Slack et al., 1951, 1955; Snyder et al., 1967), complement fixation (Kwapinski and Snyder, 1961; Snyder et al., 1967), cell-wall agglutination (Bowden and Fillery, 1978; Cummins, 1962, 1970; Fillery et al., 1978; Putnins and Bowden, 1993), immunofluorescence (Bellack and Jordan, 1972; Brock and Georg, 1969b; Buchanan et al., 1984; Cato et al., 1984; Holmberg and Forsum, 1973; Johnson et al., 1990; Lai and Listgarten, 1979; Lambert et al., 1967; Marucha et al., 1978; Schaal and Gatzer, 1985; Schaal and Pulverer, 1973; Slack and Gerencser, 1966, 1970, 1975; Slack et al., 1961, 1966), immunoassay (Gillis and Thompson, 1978), immunodiffusion (Bellack and Jordan, 1972; Bowden et al., 1976; Georg et al., 1968; King and Meyer, 1963; Schaal and Gatzer, 1985; Snyder et al., 1967), immunoelectrophoresis (Bowden et al., 1976; Fillery et al., 1978; Holmberg et al., 1975), immunoblotting (Putnins and Bowden, 1993), passive hemagglutination (Wicken et al., 1978), and immunoelectron microscopy (Garant et al., 1979) procedures have all been used to elucidate the antigenic structure of *Actinomyces* species, to define the serological relationships between species and serovars, and to locate antigenic determinants in or on *Actinomyces* cells. Among these techniques, cell-wall agglutination, immunodiffusion, immunoblotting, and fluorescent antibody tests have proved especially useful for application to the fermentative actinomycetes. Immunofluorescence has been employed most extensively, and the majority of data reported below are based upon direct or indirect modifications of this technique.

The species *Actinomyces bovis*, *Actinomyces israelii*, *Actinomyces meyeri*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, and *Actinomyces viscosus*, were all considered to be serologically heterogeneous in previous studies and were therefore subdivided into two or more serovars (Brock and Georg, 1969a; Cato et al., 1984; Slack and Gerencser, 1975). Varying degrees of cross-reactivity between the serovars within one species and between different species were noted, but there has always been general agreement that species and serovar-specific antigens do exist (Bowden et al., 1976; Schaal and Gatzer, 1985; Slack and Gerencser, 1975). Furthermore, a certain variability within some of the serovars and significant serological differences between the subclusters of the *Actinomyces israelii* phenon delineated by numerical taxonomy (Schaal and Gatzer, 1985; Schofield and Schaal, 1981) appear to indicate that additional serovars might exist. This might be of particular importance since the two original serovars of *Actinomyces israelii* have been assigned to two different species, namely *Actinomyces israelii* corresponding to *Actinomyces israelii* serovar I strains and *Actinomyces gerencseriae* which represents the former *Actinomyces israelii* serovar II strains (Johnson et al., 1990).

Serological grouping of members of the genus *Actinomyces* was first introduced by Slack and co-workers (Slack and Gerencser, 1966, 1970; Slack et al., 1961) and these serological groups could be related later on to the various *Actinomyces* species known at that time. Depending on the quality of antisera and the serological techniques used, species and/or serovar-specific antisera can be obtained either by simple dilution or by absorption procedures (Johnson et al., 1990; Marucha et al., 1978; Putnins and Bowden, 1993; Schaal and Gatzer, 1985; Schaal and Pulverer, 1973; Slack and Gerencser, 1975).

Actinomyces bovis shows no or only low grade cross-reactions with other species or between the two serovars known among strains of this species for a long time (Johnson et al., 1990; Schaal and Gatzer, 1985; Slack and Gerencser, 1975). From the comparatively small number of strains studied so far, it can be concluded that *Actinomyces bovis* serovar I strains usually produce smooth, non-filamentous microcolonies (Figure 35), whereas

serovar II microcolonies are often definitely filamentous (Slack and Gerencser, 1975) (Figure 39).

Serological heterogeneity of the taxon *Actinomyces israelii* as originally described (Lachner-Sandoval, 1898) had already been assumed by Lentze (1938a). The existence of two serovars was first reported by Lambert et al. (1967) and confirmed by Blank and Georg (1968), Brock and Georg (1969a, 1969b), Slack et al. (1969), Cummins (1970), and Schaal and Pulverer (1973). Cross-reactions occur between these two serovars which are now considered separate species. However, Brock and Georg (1969b) found only one-way cross-reactions in which serovar I (*Actinomyces israelii sensu stricto*) reacted with serovar II cells (*Actinomyces gerencseriae*), while others (Holmberg and Hallander, 1973; Schaal and Pulverer, 1973; Slack et al., 1969) obtained reciprocal cross-reactions.

Actinomyces israelii serovar I strains (*Actinomyces israelii sensu stricto*) were reported to exhibit antigenic variation (Bowden et al., 1976; Slack and Gerencser, 1975). When analyzing the serological reactivity of the four subclusters delineated within the *Actinomyces israelii* phenon in a numerical taxonomic study (Schofield and Schaal, 1981), Schaal and Gatzer (1985) confirmed these findings as the two serovar I strains, ATCC 10048 and ATCC 12102, were not only found in two different subclusters (1a and 1b), but also showed distinct serological reactivity. On the other hand, subcluster 1b contained both serovar I and II strains including the type strains of both *Actinomyces israelii sensu stricto* (ATCC 12102) and *Actinomyces gerencseriae* (ATCC 23860) thereby indicating that in the numerical phenetic analysis of Schofield and Schaal (1981) a clear-cut separation of *Actinomyces israelii* serovars I and II or *Actinomyces israelii sensu stricto* and *Actinomyces gerencseriae*, respectively, had not been possible. However, members of the subclusters 1c and 1d, which only contained human clinical isolates without any type or reference strain and which were phenotypically closely related to the two serovars of *Actinomyces israelii sensu lato* (*Actinomyces israelii sensu stricto* and *Actinomyces gerencseriae*), exhibited little or no cross-reactivity with each other and with members of the two defined serovars. It therefore remains to be seen whether the isolates of subclusters 1c and 1d represent additional serovars of *Actinomyces israelii* or *Actinomyces gerencseriae* or whether they are new *Actinomyces* species. Nonetheless, at least *Actinomyces israelii* as currently defined appears to be serologically heterogeneous although two (or more) distinct serovars have not been formally described. Furthermore, both *Actinomyces israelii sensu stricto* and *Actinomyces gerencseriae* may show noticeable cross-reactivity with *Actinomyces hordeovulneris*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, *Actinomyces oris* and even with *Arcanobacterium pyogenes* and *Propionibacterium propionicum* at low dilutions of the antisera (Buchanan et al., 1984; Schaal and Gatzer, 1985), although these cross-reactions are usually eliminated by further dilution or absorption (Schaal and Gatzer, 1985; Slack and Gerencser, 1975).

Serological differences between *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* strains were noted more than 30 years ago. A second serovar of *Actinomyces naeslundii sensu lato* was first reported by Bragg et al. (1972) on the basis of four strains which cross-reacted with both *Actinomyces naeslundii* serovar I (*Actinomyces naeslundii sensu stricto*) and *Actinomyces viscosus*, serovar II (*Actinomyces oris*). Further studies indicated, however, that three of these strains should be considered untyped (Bragg et al., 1975) or serovar I variants (Gerencser, 1979) and only one strain (WVU 1523 = CDC W1544 = ATCC 49339) should be accepted as serovar II. Jordan et al. (1974) described strain N 16 (WVU 820 = ATCC 49340) as serovar III of *Actinomyces naeslundii sensu lato*. This strain and a few similar isolates appeared to be more closely related to *Actinomyces naeslundii*, serovar II, than to serovar I and showed strong cross-reactions with *Actinomyces viscosus*, serovar II. These serological findings underpin the inclusion of serovars II and III of *Actinomyces naeslundii sensu lato* and of serovar II of *Actinomyces viscosus* in the new species *Actinomyces oris*. The organisms tentatively designated serovar IV of *Actinomyces naeslundii* (Gerencser and Slack, 1976) were found to be unrelated to *Actinomyces viscosus*, serovar II, and were therefore provisionally designated *Actinomyces* sp., serovar WVA 963 (Gerencser, 1979). This serovar was recently described as a separate *Actinomyces* species and named *Actinomyces johnsonii* (Henssge et al., 2009).

These findings were largely obtained using a direct immunofluorescence technique and largely confirmed using whole-cell and cell-wall agglutination as well as by immunoblotting (Putnins and Bowden, 1993). Whole-cell agglutination placed *Actinomyces viscosus*, serovar II, *Actinomyces naeslundii*, serovars II and III, as well as *Actinomyces*, serovar NV, which could not be typed by immunofluorescence, into a single group corresponding to the new species *Actinomyces oris*. *Actinomyces viscosus sensu stricto* cross-reacted weakly with this group.

The two serovars primarily recognized in the species *Actinomyces viscosus sensu lato* (Gerencser and Slack, 1969; Slack and Gerencser, 1970) differ in their ecology: serovar I strains represent the original hamster isolates of *Actinomyces viscosus*, while all of the serovar II strains originated from human sources. The latter were included in the new species *Actinomyces oris* whereas the hamster isolates (serovar I) retained the designation *Actinomyces viscosus (sensu stricto)* (Henssge et al., 2009; Johnson et al., 1990; Putnins and Bowden, 1993). Cross-reactions were reported between *Actinomyces hordeovulneris* and an antiserum to serovar I of *Actinomyces viscosus* (ATCC 15987 = *Actinomyces viscosus sensu stricto*). *Actinomyces viscosus*, serovar II, antisera (*Actinomyces oris*) showed no reaction with *Actinomyces hordeovulneris* (Buchanan et al., 1984).

The two serovars of *Actinomyces odontolyticus* described so far (Slack and Gerencser, 1970) exhibit only low grade cross-reactivity between each other (Schaal and Gatzer, 1985). However, very pronounced cross-reactions can be observed between *Actinomyces odontolyticus*, serovar II, and *Arcanobacterium pyogenes* (Schaal and Gatzer, 1985; Slack and Gerencser, 1975). Unfortunately, this cross-reactivity, which resulted in indirect immunofluorescence staining of the heterologous antigens at titers that were only one dilution below the homologous reaction (Schaal and Gatzer, 1985), has not been studied in more detail. Cross-reactions with other *Actinomyces* species are weak or do not occur at all.

The serological relationships between *Actinomyces naeslundii* genospecies 1 (*Actinomyces naeslundii sensu stricto*) and *Actinomyces naeslundii* genospecies 2 (*Actinomyces oris*) on the one hand and *Actinomyces denticolens*, *Actinomyces howellii*, and *Actinomyces slackii* on the other hand have been studied by Putnins and Bowden (1993) using cell-wall and whole-cell agglutination as well as immunoblotting. Whole-cell agglutination placed *Actinomyces viscosus* serovar II, *Actinomyces naeslundii* serovars II and

III and several other related strains in a single group thereby confirming the inclusion of these organisms in the new species *Actinomyces oris*. *Actinomyces viscosus* serovar I (*Actinomyces viscosus sensu stricto*) cross-reacted weakly with this group. *Actinomyces naeslundii* serovar I (*Actinomyces naeslundii sensu stricto*), *Actinomyces denticolens*, and *Actinomyces howellii* were distinct and appeared to be serologically homogeneous. The agglutination results for *Actinomyces slackii* were equivocal. Immunoblot analyses of cell-wall extracts developed with non-absorbed antisera showed cross-reactivity among all of the organisms tested including *Actinomyces israelii*.

As far as *Actinomyces denticolens* is concerned, preliminary immunofluorescence data obtained by Schaal and Gatzer (unpublished observation) confirm that this species represents a separate antigenic entity. Cross-reactions with antisera to several other *Actinomyces* species did not occur or were only very low-grade. In good agreement with cell-wall agglutination results (Putnins and Bowden, 1993), striking cross-reactions were not observed even with *Actinomyces naeslundii sensu lato* with which *Actinomyces denticolens* shares many physiological characters.

In principle, the various serological techniques give comparable results when applied to *Actinomyces* strains. However, the degree of cross-reactivity may vary depending on the method, the antigens, and the antisera used. Cross-reactions with members of other genera have occasionally been encountered (Schaal and Gatzer, 1985; Slack and Gerencser, 1975), but nearly always low-titered. They may be especially pronounced with cytoplasmic antigens (Kwapinski and Seeliger, 1964), but can also be demonstrated with other antigen sources including whole cells used for agglutination or immunofluorescence procedures. Apart from the striking cross-reactivity between *Actinomyces odontolyticus*, serovar II, and *Arcanobacterium pyogenes* that has been mentioned above, cross-reactions between *Actinomyces israelii* and *Actinomyces gerencseriae* on the one side and *Propionibacterium propionicum* on the other side can be observed by immunofluorescence and by the Ouchterlony technique (Schaal and Gatzer, 1985). Occasionally, *Actinomyces israelii sensu lato* may also cross-react with *Propionibacterium acnes* (Slack and Gerencser, 1975) or *Rothia dentocariosa* (Schaal and Gatzer, 1985). Similar cross-reactions may occur between *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* on the one hand and *Propionibacterium propionicum* and/or *Rothia dentocariosa* on the other hand (Schaal and Gatzer, 1985; Slack and Gerencser, 1975). *Actinomyces bovis*, serovar I, antisera show low-grade cross-staining with *Actinomyces meyeri* cells in indirect fluorescent antibody tests (Schaal and Gatzer, 1985).

Knowledge of the number, chemical composition, and cellular location of *Actinomyces* antigens has remained fragmentary although some antigens of oral *Actinomyces* strains which are or might be associated with their virulence have been characterized in more detail (Hammond et al., 1976). Antigenic components were found in the cytoplasm (Holmberg et al., 1975; Kwapinski and Snyder, 1961), in or on the cell wall (Bowden and Fillery, 1978; Bowden et al., 1976; Cummins, 1962; Fillery et al., 1978; Firtel and Fillery, 1988; Hammond et al., 1976; Powell et al., 1978; Putnins and Bowden, 1993; Wheeler and Clark, 1980; Wicken et al., 1978) and in culture supernatants (Georg et al., 1968; King and Meyer, 1963; Lambert et al., 1967).

Firtel and Fillery (1988) investigated the antigenic structure of *Actinomyces viscosus sensu lato* and *Actinomyces naeslundii sensu lato* using a set of 18 monoclonal antibodies against whole cells of these species. These antibodies identified 11 different antigenic determinants which were arranged in a complicated mosaic. The profiles derived from the application of these 18 monoclonal antibodies corresponded at least to some extent to the distinctions made within the *Actinomyces naeslundii/Actinomyces viscosus* complex by DNA hybridization experiments (Johnson et al., 1990), which finally led to the description of *Actinomyces naeslundii sensu stricto*, *Actinomyces viscosus sensu stricto*, *Actinomyces oris*, and *Actinomyces johnsonii* (Henssge et al., 2009).

One group of *Actinomyces* antigens consists of cell-wall associated carbohydrates or polysaccharides which may be released into the culture fluid (Bowden and Hardie, 1973; Bowden et al., 1976; Cummins, 1962; King and Meyer, 1963; Pirtle et al., 1965). These antigens are usually heat stable and resistant to treatment with proteases. They may carry species and serovar specificity (Bowden and Hardie, 1973; Bowden et al., 1976; Cummins, 1962; Putnins and Bowden, 1993). Wicken et al. (1978) characterized an amphipathic antigen of *Actinomyces viscosus* Ny 1 in more detail. This antigen was found to be a fatty acid-substituted heteropolysaccharide which accounted for 1% of the cell mass. It contained 16.8% (by weight) *O*-esterified fatty acids ($C_{16:0}$, $C_{18:0}$, $C_{18:1}$) and a polysaccharide composed of mannose, glucose, and galactose in a molar ratio of 1:2:3. Glycerophosphate, *N*-acetylgalactosamine, alanine, and lysine were further constituents, but 6-deoxytalose and rhamnose were not identified. Evidence for the presence of lipoteichoic acids was not found.

In contrast, Hammond et al. (1976) characterized a virulence-associated, high molecular mass antigen of *Actinomyces viscosus* T14-V and *Actinomyces naeslundii sensu stricto* that was composed of a polysaccharide moiety containing 6-deoxytalose as the major sugar and as determinant of serologic specificity, and a small peptide resembling to some extent part of the peptidoglycan.

Landfried (1972) isolated an antigen from the culture supernate of *Actinomyces israelii* ATCC 12102 which was non-migratory in immunoelectrophoresis and was detected in several strains of both *Actinomyces israelii* and *Actinomyces gerencseriae*. Chemical analysis indicated that this antigen might be a glycan or a mixture of two or three glycans. The peptidoglycan itself may also possess antigenic properties (Hammond et al., 1976; Reed, 1972).

A second group of *Actinomyces* antigens is composed of polypeptides or polypeptide-containing compounds (Bowden and Hardie, 1973; Bowden et al., 1976; Putnins and Bowden, 1993). These were found to be pronase-sensitive, but trypsin resistant, charged molecules which were species-specific although they contained cross-reacting components. Employing two-dimensional (crossed) immunoelectrophoresis, Ayakawa et al. (1983) identified a major heat-stable surface antigen in *Actinomyces israelii* serovar II (*Actinomyces gerencseriae*) which was protease-sensitive, non-dialyzable, and found in relatively large amounts. *Actinomyces israelii sensu stricto* lacked this antigen or contained small amounts of a cross-reacting antigen which was not identical with the *Actinomyces gerencseriae* component. Despite its heat-stable property, the antigen was assumed to be, at least in part, a protein. Trypsin digestion split the antigen into two components with considerably faster electrophoretic mobilities than the original antigen.

The cytoplasmic antigens prepared by Kwapinski and Snyder (1961) exhibited pronounced cross-reactivity. In contrast, Holmberg et al. (1975) reported that the crossed immunoelectrophoresis or crossed immunoelectrofocusing of their cytoplasmic preparations gave specific and reproducible results. It can be assumed that at least some of the cytoplasmic antigens are proteins or polypeptides.

The proteinaceous nature has been proven for the virulence-associated antigen 1 of *Actinomyces viscosus* T14V (Cisar and Vatter, 1979; Cisar et al., 1978; Wheeler and Clark, 1980) which is identical with the fimbriae (type 1 fimbriae) produced by this organism. These fimbriae were reported (Wheeler and Clark, 1980) to consist of 95.2% protein and less than 2% carbohydrate and contained large quantities of aspartic acid, threonine, glutamic acid, and alanine. A minimum molecular mass of 24,960 was calculated for this fimbrial protein.

The antigens on type 2 fimbriae differ clearly from those of type 1 fimbriae so that the different attachment properties mediated by each of the two fimbrial types can be inhibited separately by specific neutralizing antibodies (Cisar et al., 1988; Revis et al., 1982).

Susceptibility to antibiotics and various chemical compounds. *Actinomyces* species display a moderate to high susceptibility to many of the antibacterial drugs currently in use, thereby showing comparatively little species and strain variation (Abrahams and Miller, 1946; Blake, 1964; Buchanan et al., 1984; Cato et al., 1984; Chow and Bednorz, 1978; Fritsche, 1964a; Hanf, 1956; Hanf et al., 1953; Howell, 1953; Lentze, 1957, 1967; Lerner, 1967, 1974; Niederau et al., 1982; Schaal and Pape, 1980; Schaal et al., 1979; Smith et al., 2005; Spieckermann, 1970; Suter and Vaughan, 1955; Sutter and Finegold, 1976). A tendency towards an increasing antibiotic resistance of these actinomycetes has as yet never been documented with sufficient certainty. However, susceptibility results obtained in different laboratories often differ considerably even though certain reference strains were common to many studies. This indicates that methodological problems obviously play an important role in the assessment of drug susceptibility of fermentative actinomycetes (Schaal and Pape, 1980; Schaal et al., 2006).

In susceptibility testing of fermentative actinomycetes, the only procedure found to give reproducible and clinically useful results is the agar dilution test using DST agar (Oxoid) as test medium and microscopic assessment of results after only 24 (at maximum 48) hours of incubation (Schaal and Pape, 1980). The different growth rate and degrees of filament formation usually do not allow sufficient standardization of the agar dilution or broth dilution tests, respectively. Whether the E-test methodology is applicable to all of the *Actinomyces* species known so far remains unproven. The results obtained by Smith et al. (2005) using this technique appear to indicate that filamentous and slowly growing species might be more susceptible than the same species tested by the agar dilution method. Which of these differing results is clinically more relevant awaits clarification.

The minimal inhibitory concentrations (MICs; <0.016–3.12 mg/l) reported for *Actinomyces bovis*, *Actinomyces europaeus*, *Actinomyces funkei*, *Actinomyces graevenitzii*, *Actinomyces israelii sensu lato* as well as for *Actinomyces israelii sensu stricto*, and *Actinomyces gerencseriae*, *Actinomyces naeslundii sensu lato*, *Actinomyces viscosus sensu lato*, and *Actinomyces turicensis* reveal that all of these species are usually highly susceptible to β-lactam antibiotics (penicillins, cephalosporins, and carbapenems) (Niederau et al., 1982; Schaal and Pape, 1980; Schaal et al., 1979; Smith et al., 2005). This also applies to the combinations of β-lactams and β-lactamase inhibitors such as amoxicillin plus clavulanic acid, ampicillin plus sulbactam, and piperacillin plus tazobactam. However, Smith et al. (2005) using the E-test found that two *Actinomyces europaeus*, five *Actinomyces funkei*, and nine *Actinomyces turicensis* strains displayed reduced susceptibility (≥1 mg/l) to piperacillin/tazobactam.

Tetracyclines, chloramphenicols, macrolides, lincomycins, rifamycins, fusidic acid, and glycopeptide antibiotics (vancomycin and teicoplanin) also exhibit a moderate to high inhibitory activity against all of the "classical" *Actinomyces* species (Niederau et al., 1982; Schaal and Pape, 1980; Schaal et al., 1979). As far as the newer members of the genus are concerned, 2 of 10 *Actinomyces europaeus* and 2 of 11 *Actinomyces turicensis* isolates showed resistance to erythromycin (Smith et al., 2005).

All isolates of *Actinomyces europaeus*, *Actinomyces funkei*, *Actinomyces gerencseriae*, *Actinomyces graevenitzii*, *Actinomyces israelii*, and *Actinomyces turicensis* tested by Smith et al. (2005) were reported to be resistant to ciprofloxacin. In contrast, all but three of 87 isolates of the above six species were found to be susceptible to linezolid. The three strains having MICs of >1.0 mg/l comprised one *Actinomyces europaeus* and two *Actinomyces turicensis* isolates. *Actinomyces radingae* and *Actinomyces turicensis* were both found to be resistant to mupirocin (Vandamme et al., 1998).

MICs for *Actinomyces hordeovulneris* were reported as follows: penicillin G, ≤0.25 mg/l; chloramphenicol, 1.0 mg/l; cotrimoxazole, 1.0 mg/l; tetracycline, 0.5–4.0 mg/l. All strains of *Actinomyces meyeri* tested so far were susceptible to chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracyclines (Cato et al., 1984).

Complete resistance has only been observed to aminoglycosides, nitroimidazole compounds, polypeptide antibiotics (polymyxin B, colistin), antifungal drugs, and certain antituberculotics (Niederau et al., 1982; Suter and Vaughan, 1955). Susceptibility data for the remaining newer *Actinomyces* species are not available.

The resistance patterns of members of the genus *Actinomyces* to other chemical and biological inhibitory or toxic compounds are as follows: sodium chloride at a concentration of 2% (w/v) was found to be inhibitory only to *Actinomyces odontolyticus*, while many strains of *Actinomyces bovis*, *Actinomyces israelii sensu lato*, *Actinomyces meyeri*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato* were able to grow at this concentration. Certain *Actinomyces meyeri*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato* strains also tolerated 4% (w/v) NaCl, but 6% inhibited growth of all of the *Actinomyces* isolates tested. Bile at concentrations of 5 and 10% (w/v) inhibited many *Actinomyces bovis*, *Actinomyces israelii sensu lato*, *Actinomyces meyeri*, and all of the *Actinomyces odontolyticus* strains, whereas *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* isolates were resistant. Even at 20% bile, about one half of the *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* strains were able to grow. The results obtained with sodium taurocholate (0.2%, w/v) were at variance to these findings. Sodium selenite (0.01%, w/v) caused complete growth inhibition of the majority of the *Actinomyces israelii sensu lato* and *Actinomyces odontolyticus* strains tested while about one third of the *Actinomyces bovis*, *Actinomyces naeslundii sensu lato*,

and *Actinomyces viscosus sensu lato* isolates grew in the presence of this inhibitor. Potassium tellurite (0.01%, w/v) and sodium azide (0.005%, w/v) were tolerated by most of the *Actinomyces* strains except *Actinomyces radingae* and *Actinomyces turicensis* isolates, whereas crystal violet (0.005%, w/v) inhibited all of the *Actinomyces israelii sensu lato* and *Actinomyces odontolyticus* strains and many of the *Actinomyces bovis*, *Actinomyces naeslundii sensu lato*, and *Actinomyces viscosus sensu lato* isolates tested (Cato et al., 1984; Schofield and Schaal, 1981; Vandamme et al., 1998).

Trace element requirements. Gallagher and Cutress (1977) studied the effect of trace elements on growth and fermentation of *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato*, and found that sodium selenite (50 ppm) inhibited growth and acid production of both species groups tested. This is in accord with the results of Schofield and Schaal (1981). Similar inhibitory effects were obtained with sodium fluoride (1000 ppm), manganous chloride (500 ppm), zinc sulfate (400 ppm), strontium chloride (10,000 ppm, only *Actinomyces viscosus sensu lato*), silver nitrate (30 ppm), and antimony potassium tartrate (100 ppm). Ammonium vanadate (12.5 ppm), nickelous chloride (100 ppm), copper sulfate (200 ppm), cadmium iodide (2 ppm), and barium chloride (400 ppm) showed no, or only slight, inhibition of growth and/or acid production.

Pathogenicity. Since the description of the first member of the genus *Actinomyces*, namely *Actinomyces bovis* (Bollinger, 1877), it has been known that fermentative actinomycetes can cause various forms of potentially severe inflammatory diseases in man, as well as in feral, domestic, and laboratory animals. However, virulence, types of pathological lesions induced, and host specificity vary considerably between members of different *Actinomyces* species (Schaal, 1979, 1981; Schaal and Beaman, 1984; Schaal and Pulverer, 1981; Schaal et al., 2006; Slack, 1974; Slack and Gerencser, 1975). Essentially all of these pathogenic actinomycetes apparently belong to the normal indigenous microflora of their respective hosts, so that they must be considered facultative rather than obligate pathogens that only invade tissue under certain facilitating conditions and are usually not transmissible (Lentze, 1938a, 1938b, 1969; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984b, 1984a; Schaal, 1979, 1986b; Schaal, 1996; Schaal, 1998; Schaal and Beaman, 1984; Schaal and Pulverer, 1984; Schaal and Lee, 1992; Schaal et al., 2006; Slack and Gerencser, 1975). These facilitating conditions do not necessarily include dysfunctions of the host's immune system!

Human diseases and impairments. Typical diseases and impairments caused by *Actinomyces* species in humans are: actinomycoses, lacrimal canaliculitis and other ocular infections, periodontal disease, caries, and intrauterine infections. Among these pathological conditions, actinomycoses are undoubtedly the most characteristic disease entities caused by members of the genus *Actinomyces* in humans.

As currently recognized, actinomycoses are endogenous, subacute to chronic, granulomatous inflammatory processes that give rise to suppuration, abscess formation, and development of draining sinus tracts (Pulverer and Schaal, 1978, 1984a, 1984b; Schaal, 1979, 1996, 1998; Schaal and Beaman, 1984; Schaal et al., 2006; Slack and Gerencser, 1975). The etiology of actinomycotic infections is complex in two respects: i) Clinically typical human actinomycoses are produced not only by several *Actinomyces* species but also by *Propionibacterium propionicum*, and, rarely, by *Bifidobacterium dentium*. ii) Apart from the causative actinomycetes, additional microbes, so-called concomitant bacteria, are associated with actinomycoses (Holm, 1950, 1951; Lentze, 1948, 1953, 1969; Pulverer and Schaal, 1978; Pulverer et al., 2003; Schaal, 1979, 1981, 1985a, 1986a, 1986b, 1996, 1998; Schaal and Beaman, 1984; Schaal and Pulverer, 1981, 1984; Schaal and Lee, 1992; Schaal et al., 1984, 2006). Although *Aggregatibacter actinomycetemcomitans* may be considered the most characteristic companion of the actinomycetes, other companions include various Gram-stain-negative and Gram-stain-positive bacterial species. The composition of this mixed flora varies from case to case, but is always present to boost the relatively low invasive potential of the causative actinomycetes.

In 10–25% of cases, depending on the course of the disease (Pulverer and Schaal, 1978, 1984a, 1984b; Pulverer et al., 2003; Schaal, 1979, 1981; Schaal, 1996, 1998; Schaal and Beaman, 1984; Schaal et al., 2006), the purulent discharge from actinomycotic lesions contains macroscopically visible (≤1 mm in diameter), yellowish to brownish or reddish particles (usually referred to as "Drusen" or "sulfur granules") that are conglomerates of filamentous actinomycete microcolonies formed *in vivo*, various other bacteria, and tissue reaction material, especially polymorphonuclear granulocytes, surrounding the microbial center (Schaal et al., 2006). Corresponding filamentous colony-like structures are commonly found in tissue sections, but are often smaller than those from pus and usually show a club-shaped layer of hyaline material on the tips of peripheral hyphae (Schaal and Beaman, 1984; Schaal et al., 2006; Slack and Gerencser, 1975). The chemical composition of this hyaline material, though not elucidated in detail, is a polysaccharide-protein complex containing high concentrations of various salts (Crawford, 1971; Frazier and Fowler, 1967; Pine and Overman, 1966; Widra, 1963). It should also be noted that morphology and chemical composition of human and animal sulfur granules are apparently not completely identical (Schaal et al., 2006).

Human actinomycoses most frequently affect the face and neck, the cervicofacial area, but they may also be encountered in thoracic and abdominal or pelvic sites (Lentze, 1938a, 1948, 1953, 1969, 1970, 1971; Pulverer and Schaal, 1978; Pulverer et al., 2003; Schaal, 1979, 1981; Schaal and Beaman, 1984; Schaal and Pulverer, 1981; Schaal et al., 2006; Slack and Gerencser, 1975; Wolff and Israel, 1891). Cervicofacial actinomycoses predominantly develop in the soft tissue around the mandible, but they may also be found adjacent to the maxilla or may extend to the orbita, the sinuses, the ear, or the neck (Olson et al., 1989; Pape et al., 1984). Even primary actinomycoses of the thyroid gland have been observed (Dan et al., 1984).

In contrast to animal actinomycoses, human actinomycoses rarely affect the skeleton (Schaal et al., 2006). However, actinomycotic osteitis or osteomyelitis of the mandible, the maxillae, and even the humerus, the temporal bone, the skull, a phalanx of the big toe (Toumi et al., 2005), and the vertebrae have been reported sporadically (Gupta et al., 1986; Honda et al., 2008; Kannangara et al., 1981; King et al., 1998; Kumar et al., 2008; Mehta et al., 2007; Mtaallah et al., 2005; Slack and Gerencser, 1975; Vannier et al., 1986; Winston, 1951; Yenson et al., 1983). Furthermore, recent observations suggest that osteoradionecrosis and biphosphonate-associated osteonecrosis of the jaw greatly promote the development of actinomycotic

osseous infections (Danic et al., 2008; Hansen et al., 2006a; Hansen et al., 2007; Hansen et al., 2006; Magremanne et al., 2006).

Thoracic actinomycoses usually have a history of preceding cervicofacial lesions or of aspiration, but may also develop hematogenously. Their incidence appears to be much higher in the U.S.A. than in Europe, but difficulties in diagnosing the disease may contribute to this difference (Kedmi et al., 2007; Massart et al., 1986; Masters et al., 1985; Philipsen et al., 1988; Schaal, 1996, 1998; Suzuki and Delisle, 1984). From the lungs, the infection may extend to the pleural space (Schaal, 1996), the pericardium (Kedmi et al., 2007), and the chest wall (Reyes, 2007), or may even track down to the groin and appear as a psoas abscess (Schaal, 1996).

The nature and clinical relevance of a disease termed “endobronchial actinomycosis” remains to be definitely clarified as nearly all of the reports on this condition that can be found in the literature were solely based upon histopathological findings without confirmation by bacteriological techniques (Chouabe et al., 2002; Jin et al., 2000; Kim et al., 2002; Lee et al., 1999; Ocal et al., 2004; Rad and Milani, 2007; Toth et al., 2007). Furthermore, it should be noted that all of these cases of so-called endobronchial actinomycoses did not display the pronounced invasiveness of typical actinomycoses and many of them were associated with foreign bodies (inhaled chicken bones, fish bones, teeth or tooth fragments, grape seeds, beans, or broncholithiasis).

Abdominal actinomycoses often follow appendicitis, abdominal trauma, injuries caused by ingested bone splinters or fish bones, bowel surgery, or laparoscopy, and may be located retro- or intraperitoneally (Adachi et al., 1985; Baierlein et al., 2007; Ghannouchi Jaafoura et al., 2008; Karagulle et al., 2008; Levine and Doyle, 1988; Wohlgemuth and Gaddy, 1986; Yamada et al., 2006). They may involve a variety of organs such as the colon (Heer et al., 1986; Saha et al., 2007), the rectum (Stein and Schaal, 1987), the perianal tissue (Gayraud et al., 2000; Shimada et al., 1986), the gallbladder (Lee et al., 2009; Lee et al., 2007; van Steensel and Kwan, 1988), the liver (Braun et al., 2009; Forgan-Smith et al., 1989; Logan et al., 1989; Mongiardo et al., 1986; Yamashita et al., 2007), the kidneys (Homberg et al., 2008; Yenarkarn et al., 2007), the urinary bladder with sulfur granules in the urine (Wajszczuk et al., 1984), and the spleen (Jabr and Skeik, 2007).

The incidence of pelvic infections appears to be increasing in recent years and this is obviously related to the widespread use of intrauterine contraceptive devices (IUCDs), vaginal pessaries, or tampons (Barnham et al., 1978; Bhagavan and Gupta, 1978; Drew, 1981; Gupta et al., 1978; Hager and Majmudar, 1979; Hart et al., 1977; Kohoutek and Nozicka, 1978; Pine et al., 1985; Szabo et al., 1981; Witwer et al., 1977). But pelvic actinomycoses can apparently also be induced by other foreign bodies such as retained intrauterine fetal bones (White and Felix, 2007). Pelvic infections may remain restricted to tissue in the small pelvis (uterus, Fallopian tubes, ovaries), but also may spread continuously or hematogenously to the liver and other intra-abdominal organs or to the abdominal wall (Brihmer et al., 1987; Eibach et al., 1992; Harmouch et al., 2008; Kaszuba et al., 2008; Lininger and Frable, 1984; Mtaallah et al., 2005; Mubiayi et al., 2007; O’Connor et al., 1989; Peitsidis et al., 2008; Persson and Christina, 1986; Shurbaji et al., 1987; Taga, 2007; White and Felix, 2007). Even involvement of the placenta has been observed (Zakut et al., 1987).

Actinomycoses of the central nervous system (CNS) are rare and may either develop hematogenously from distant sites (lung, abdomen, pelvis) or by direct extension from contiguous foci such as ears, orbital cavity, sinuses, or cervicofacial lesions (Fetter et al., 1967; Hutton and Behrens, 1979; Koshi et al., 1981; Nithyanandam et al., 2001; Slack and Gerencser, 1975; Smego, 1987; Stevenson and Gossman, 1968). The types of CNS lesions include brain or cerebellar abscess, meningitis or meningoencephalitis, subdural empyema, and epidural abscess (Benito León et al., 1998; Peacock et al., 1984; Prager et al., 1984; Schwarz et al., 1993; Smego, 1987; Soto-Hernándes et al., 1999; Tsai et al., 2001; Tvede et al., 1985; Winking et al., 1996).

Primary actinomycoses of the skin and the extremities are also very rare and usually have a history of trauma resulting from human bites or fist fights (“punch actinomycosis”) thereby representing the only exogenously acquired forms of the disease (Slack and Gerencser, 1975; Southwick and Lister, 1979). These infections are usually located on the hands or arms, but may also be found on the back (Patil et al., 2008). Hematogenous dissemination to the soft tissue, the bones, or the joints of the extremities have been observed (Blinkhorn et al., 1988; Legum et al., 1978; Mesgarzadeh et al., 1986; Reiner et al., 1987) and even a total hip arthroplasty was found to be infected with fermentative actinomycetes (Strazzeri and Anzel, 1986). The detailed pathogenesis of lesions of the vulva that were suspected of being malignant, but appeared to have been caused by *Actinomyces israelii* in co-infection with *Propionibacterium acnes* and *Peptostreptococcus* sp. remains to be clarified (McElroy et al., 2006).

The predominant causative agents of human actinomycoses are *Actinomyces israelii* and *Actinomyces gerencseriae* (Lentze, 1969; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984b; Pulverer et al., 2003; Schaal, 1981; Schaal and Lee, 1992; Schaal and Pulverer, 1973; Schaal et al., 2006; Slack and Gerencser, 1975; Wolff and Israel, 1891). In addition, *Propionibacterium propionicum* is also a typical causative agent of the disease (Brock et al., 1973; Conrad et al., 1978; Gerencser and Slack, 1967; Pulverer and Schaal, 1978, 1984a, 1984b; Pulverer et al., 2003; Schaal, 1979, 1981, 1985a, 1986a, 1988; Schaal and Lee, 1992; Schaal et al., 2006; Slack and Gerencser, 1975). Other *Actinomyces* species may occasionally be isolated from characteristic human actinomycotic lesions. *Actinomyces naeslundii sensu lato* has been recovered comparatively frequently from cervicofacial infections (Pulverer and Schaal, 1978; Pulverer et al., 2003; Schaal, 1979, 1981; Schaal, 1984; Schaal and Lee, 1992) and sporadically from pulmonary (Karetzky and Garvey, 1974) and abdominal (Scharfen, 1975) lesions. Similarly, *Actinomyces viscosus sensu lato* has been recovered from cervicofacial (Larsen et al., 1978; Pulverer et al., 2003; Schaal, 1979, 1981; Schaal and Lee, 1992) and thoracic (Eng et al., 1981; Lewis and Gorbach, 1972; Mosimann et al., 1979; Spiegel and Telford, 1984; Thadepalli and Rao, 1979) actinomycoses. It should be kept in mind, however, that these actinomycetes may be found in mixed culture together with *Actinomyces israelii* or *Actinomyces gerencseriae* so that their etiological role in a given case of human actinomycosis may be questioned (Schaal et al., 2006). *Actinomyces odontolyticus* appears to be rarely involved in the etiology of invasive infections although this species has been isolated from a few cases of cervicofacial lesions (Mitchell et al., 1977; Pulverer

et al., 2003; Schaal and Pulverer, 1984; Schaal and Lee, 1992) and from pleural fluid and lung abscesses, respectively (Baron et al., 1979; Guillou et al., 1977). *Actinomyces meyeri* has been isolated frequently from brain abscesses and pleural fluid and less often from cervicofacial suppurations and bite wounds (Cato et al., 1984; Pulverer et al., 2003; Schaal and Lee, 1992).

Actinomycete eye infections may present as conjunctivitis, lacrimal canaliculitis, dacryocystitis, keratitis, or even intraocular infection, lacrimal canaliculitis being the most characteristic disease entity among these conditions. Branching, filamentous organisms in lacrimal concretions were already described by Ferdinand Cohn in (1875). Detailed bacteriological examinations revealed that these filamentous microbes can be identified as *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, *Actinomyces viscosus sensu lato*, *Propionibacterium propionicum*, *Bifidobacterium dentium*, *Rothia dentocariosa*, and even as *Nocardia farcinica* (Blanksma and Slijper, 1977; Buchanan and Pine, 1962; Ellis et al., 1961; Jones and Robinson, 1977; Pine and Hardin, 1959; Pine et al., 1960; Schaal, 1986a, 1988; Schaal and Pulverer, 1984; Schaal and Lee, 1992; Schütt-Gerowitt et al., 1999; Slack and Gerencser, 1975; Takemura et al., 2002). Unlike human actinomycoses, eye infections are usually not invasive, and *Propionibacterium propionicum* is the predominant causative agent of lacrimal canaliculitis followed by *Actinomyces israelii* and *Actinomyces gerencseriae* (Schaal, 1986a; Schaal and Lee, 1992; Schütt-Gerowitt et al., 1999). The etiology of the other inflammatory processes of the eye mentioned above differs to some extent from that of canaliculitis in that *Actinomyces naeslundii sensu lato*, *Actinomyces viscosus sensu lato*, and *Actinomyces odontolyticus* appear to be the prevailing causative agents (Schaal, 1988; Schaal and Lee, 1992; Schütt-Gerowitt et al., 1999). Even two different *Actinomyces* species, such as *Actinomyces israelii* and *Actinomyces naeslundii sensu lato*, may be isolated from a single ocular specimen (Schaal and Pulverer, 1984).

Apart from actinomycosis and lacrimal canaliculitis which represent clinically well defined disease entities, various other inflammatory processes may be induced by *Actinomyces* species. This primarily applies to nearly all of the recently described novel species of human origin as well as to some of the classical ones. Although *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* have been recovered rather frequently from actinomycosis-like lesions (Pulverer et al., 2003; Schaal and Lee, 1992), a study of such infections (comparing the ways of obtaining specimens for bacteriological culture [intraoral incision/puncture vs extraoral incision/puncture]) showed that the isolation of these two species was often related to contamination of the specimen with oral secretions (Schaal and Pulverer, 1984). Furthermore, *Actinomyces naeslundii* or *Actinomyces viscosus* may occasionally be isolated together with *Actinomyces gerencseriae*, *Actinomyces israelii*, or *Propionibacterium propionicum* so that the etiological role of the former species remains obscure in these instances, especially in cases of clinically characteristic actinomycoses (Pulverer et al., 2003). However, *Actinomyces naeslundii sensu lato* has been convincingly reported as a causative agent of gallbladder infections (Freland et al., 1987), pelvic infections (Bonnez et al., 1985), a disseminating infection in a mentally retarded child (Dobson and Edwards, 1987), of a recurring empyema of the knee joint (Schaal and Pulverer, 1984), and of an infection of a total knee arthroplasty (Ruhe et al., 2001) and a hip prosthesis (Wüst et al., 2000).

Apart from its involvement in cervicofacial and pulmonary infections, *Actinomyces viscosus sensu lato* has been isolated from an abscess following a dog bite (del Carmen Pinilla and Ciniglio, 1983), and even from blood samples of patients with endocarditis (Mardis and Many, 2001).

The number of reports on human *Actinomyces odontolyticus* infections appears to have increased recently. Schaal and Lee (1992) found that 1.8% of all actinomycete isolates encountered belonged to this species. Clinically, *Actinomyces odontolyticus* infections should not be termed actinomycoses (Klaaborg et al., 1985; Peloux et al., 1983). Nonetheless, various types of inflammatory processes have been attributed to *Actinomyces odontolyticus*: an ulcer of the oral mucosa (Alamillos-Granados et al., 2000), peritonsillar abscesses (Civen et al., 1993), enterocutaneous fistulation (Klaaborg et al., 1985), multiple liver abscesses (Ruutu et al., 1982), thoracic infections including lung infections with and without extension to the pleural space, to the mediastinum, or the pericardium (Baron et al., 1979; Bassiri et al., 1996; Dontfraid and Ramphal, 1994; Hooi et al., 1992; Ibanez-Nolla et al., 1993; Litwin et al., 1999; Perez-Castrillon et al., 1997; Verrot et al., 1993), brain abscess (Simpson et al., 1996), and even septicemia (Raoult et al., 1982).

Actinomyces meyeri has been isolated frequently from brain abscesses and pleural fluid (Cato et al., 1984) and less often from cervicofacial abscesses (Pordy, 1988), lung and breast abscesses (Allen, 1987; Ferrier et al., 1986; Rippon and Kathuria, 1984; Rose et al., 1982), pneumonitis (Allworth et al., 1986), and abscesses with and without osteomyelitis of hip, symphysis pubis, leg, and foot (Cato et al., 1984; Ferrier et al., 1986; Long et al., 2007; Machet et al., 1993; Pang and Abdalla, 1987), as well as from spleen, liver, or perianal infections, and infected bite wounds (Bauer et al., 2006; Cato et al., 1984; Garcia-Corbeira and Esteban-Moreno, 1994; Garduño et al., 2000; Gayraud et al., 2000; Harsch et al., 2001). A striking tendency of the organism to disseminate has led to involvement of various other organs including heart valves, spleen, or brain (Apotheloz and Regamey, 1996; Chaumentin et al., 1997; Colmegna et al., 2003; Ferrier et al., 1986; Garduño et al., 2000; Huang et al., 1998; Kuijper et al., 1992; Lentino et al., 1985; Marty and Wüst, 1989; van Mook et al., 1997). An infection of the umbilical cord has also been described (Wright et al., 1994).

Actinomyces radingae and *Actinomyces turicensis* have been primarily isolated from various polymicrobial infections (Wüst et al., 1995a), but occasionally also as pure cultures (Clarridge and Zhang, 2002). More recent studies by Vandamme et al. (1998), Sabbe et al. (1999), and Clarridge and Zhang (2002) revealed that human *Actinomyces radingae* infections are relatively rare and mostly present as skin-related processes and soft tissue conditions including perineal abscesses, an infected pilonidal cyst, pleural empyema, and axillar hydradenitis (Junquera-Bañares and Sanz-de La Fuente, 2007; Lepe et al., 1998). In contrast, *Actinomyces turicensis* infections appear to be quite common and usually involve the urogenital tract and the skin (Clarridge and Zhang, 2002; Sabbe et al., 1999; Zautner et al., 2009). In addition, appendicitis, cholecystitis, hepatic abscess, ear, nose and throat infections, breast abscesses, vaginal infections, vulvar abscesses, as well as bacteremia due to *Actinomyces turicensis* or double infections together with *Actinomyces radingae*, may be observed (Attar et al., 2007; Riegert-Johnson et al., 2002; Sabbe et al., 1999; Vandamme et al., 1998).

The two subspecies of *Actinomyces neuii* have been mainly isolated from abscesses or infected atheromas in association with mixed anaerobic flora and from human blood cultures (Funke et al., 1994; Funke and von Graevenitz, 1995), but not from typical actinomycotic lesions. The organism has also been recovered from infected mammary prostheses (Brunner et al., 2000), chronic osteomyelitis (Van Bosterhaut et al., 2002), postoperative endophthalmitis (Garelick et al., 2002; Perez-Santonja et al., 2007; Raman et al., 2004), neonatal sepsis following chorioamnionitis (Mann et al., 2002), infective endocarditis (Cohen et al., 2007), and from a ventriculoperitoneal shunt infection (Watkins et al., 2008).

Actinomyces europaeus has been cultured from abscesses at various locations (breast, suprapubic, perianal, and labial abscesses), but also from femur tissue, decubital ulcers, and an atheroma cyst (Clarridge and Zhang, 2002; Funke et al., 1997a; Sabbe et al., 1999). It has also been recovered from patients suffering from urinary tract infections (Sabbe et al., 1999) and, together with *Actinomyces turicensis*, from subcutaneous fistulae in a patient with femoral hypoplasia (Zautner et al., 2009).

The four isolates of *Actinomyces graevenitzii* reported upon in its original description had been isolated from bronchial secretions (three strains) and osteitis material (one strain) (Pascual Ramos et al., 1997a). In addition, a case of disseminated coinfection with *Actinomyces graevenitzii* and *Mycobacterium tuberculosis* as causal agents has been recently published (Tietz et al., 2005). *Actinomyces radicidentis* was derived from infected root canals of human teeth (Collins et al., 2000; Kalfas et al., 2001) although the role played by this species in endodontic infections has not been fully clarified (Siqueira and Rocas, 2003). Nevertheless, *Actinomyces radicidentis* was shown to form large aggregates of cells held together within extracellular matrix where it may more easily evade host defense mechanisms (Nair et al., 2008). *Actinomyces urogenitalis* has been primarily isolated from samples from the human urogenital tract such as urine, and urethral and vaginal secretions (Nikolaitchouk et al., 2000); recently, this species was found to be etiologically involved in a penis ulcer (Schaal, unpublished observation) and in an intrauterine contraceptive device-associated pelvic actinomycosis (Elsayed et al., 2006). The three strains of *Actinomyces funkei* reported so far were derived from a case of human tricuspid valve endocarditis of a female intravenous drug user, a sternum wound, and an abdominal incision (Lawson et al., 2001b; Westling et al., 2002). The eight isolates of *Actinomyces cardiffensis* described to date originated from intrauterine contraceptive devices without reported signs of inflammation (three strains), from multiple abscesses in a patient four weeks after mastoidectomy together with a complex concomitant flora, from pleural fluid of a patient suffering from shortness of breath and wheezing, from pus of an actinomycotic jaw abscess, from a pericolic abscess, and from a right antral washout of a patient with sinusitis (Hall et al., 2002). The single strains described as *Actinomyces nasicola* (Hall et al., 2003d), *Actinomyces oricola* (Hall et al., 2002), *Actinomyces dentalis* (Hall et al., 2005), *Actinomyces hongkongensis* (Woo et al., 2003), and *Actinomyces massiliensis* (Renvoise et al., 2009) originated from pus from the nasal antrum, two dental abscesses, a patient with suspected pelvic actinomycosis, and a blood culture from a patient with pleuropneumonia, respectively.

Actinomyces georgiae had long been thought to be nonpathogenic to humans although it belongs, like the other *Actinomyces* species mentioned above, to the human indigenous oral microflora (Johnson et al., 1990; Schaal et al., 2006). However, a recent report appears to indicate that *Actinomyces georgiae* might be a rare agent of endocarditis (Jitmuang, 2008).

In the complex etiology of caries and periodontal disease, *Actinomyces* species apparently constitute only one link in a long chain of cause and effect. Nevertheless, evidence has been growing that at least *Actinomyces naeslundii sensu stricto*, *Actinomyces oris*, and *Actinomyces odontolyticus*, because of their adherence and coaggregation mechanisms, play an important role in the formation of dental plaque which is thought to be a prerequisite for the development of these conditions (Batty, 1958; Jordan and Hammond, 1972; Jordan and Sumney, 1973; Slack and Gerencser, 1975; Socransky, 1970; Winford and Haberman, 1966). Additional factors that might contribute to the pathogenesis of caries and periodontitis are acid production from carbohydrates (Wikström et al., 1983), mitogenicity for splenocytes including the B-cell subpopulation (Baker, 1985; Engel et al., 1984; Halfpap et al., 1985), induction of T-cell proliferation (Burckhardt, 1978), activation of the alternate complement pathway (Baker and Billy, 1983), the production of chemotactic effects and the marking of fibroblasts for immune-mediated damage (Engel et al., 1976, 1978; Wicken et al., 1978). Furthermore, the type 2 fimbrial lectin of *Actinomyces oris* was demonstrated to stimulate superoxide and lactoferrin release from polymorphonuclear leukocytes and obviously also mediates phagocytosis and subsequent killing of bacteria (Sandberg et al., 1986; Taichman et al., 1978). *Actinomyces meyeri* has been cultured from subgingival crevices in patients with severe periodontitis (Cato et al., 1984) although its etiological role in this condition remains to be definitely proven.

Apart from producing typical pelvic actinomycoses, *Actinomyces* species, in particular *Actinomyces israelii* and *Actinomyces gerencseriae*, are possibly also able to produce cervicitis and endometritis in women using IUCDs (Bhagavan and Gupta, 1978; Eibach et al., 1989; Luff et al., 1978).

Animal diseases. The best known natural *Actinomyces* infection occurring in animals is bovine actinomycosis (lumpy jaw) (Bollinger, 1877) which (as in human infections) is usually located adjacent to the mandible or maxilla, but in contrast to human infections frequently involves the bone (Slack and Gerencser, 1975). Primary lung infections in cattle have been reported (Biever et al., 1969). The principal causative agent of bovine actinomycosis is *Actinomyces bovis* which may also occur in other animals, but has never been identified with certainty in material from human lesions (Bollinger, 1877; Schaal and Beaman, 1984; Slack and Gerencser, 1975). Whether *Actinomyces vaccimaxillae* (Hall et al., 2003a) is a second agent of typical bovine actinomycoses, remains to be proven. Bovine infections caused by *Actinomyces israelii sensu lato* (Cummins and Harris, 1959; King and Meyer, 1957; Pine et al., 1960) have also been reported, but remain to be confirmed using modern identification methods. The same is true for the isolation of *Actinomyces israelii* from different organs of dead, disabled, diseased, and dying sheep (Goda et al., 1986) and for the role of *Actinomyces viscosus sensu lato* as an etiologic agent of abortion in cattle (Okewole et al., 1989).

Actinomycosis in swine appears to involve udders, lungs, or other internal organs more frequently than neck and bones (Franke, 1973; Grässer, 1957; Magnusson, 1928; Thompson,

1933). "*Actinomyces suis*" (Franke, 1973; Grässer, 1957), *Actinomyces israelii* (Magnusson, 1928), and *Actinomyces viscosus sensu lato* (Georg et al., 1972) were previously incriminated as etiologic agents of pig infections. "*Actinomyces suis*" Franke (1973) has remained a *species incertae sedis* (Schaal, 1986b). The *Actinomyces*-like isolates described by Murakami et al. (1998, 1999) appeared to differ from other actinomycetes occurring in swine, but were not described in detail. Nevertheless, one of these pig species that had been isolated from purulent discharge and resembled "*Actinomyces suis*" phenotypically, was described as *Actinomyces hyovaginalis* (Collins et al., 1993). The strains which were used for the original description of *Actinomyces hyovaginalis* were exclusively derived from purulent vaginal secretions and aborted fetuses of pigs. These were recently assigned to the "vaginal" biovar of *Actinomyces hyovaginalis*. Similar strains that could not be differentiated on the basis of 16S rRNA gene sequence similarity and which had originated from necropsy samples from a variety of body sites of pigs differed from the original isolates in colony morphology and a few physiological characteristics, and were therefore designated members of the "general" biovar of the species. A new species from pig mastitis was named *Actinomyces suimastitidis* (Hoyles et al., 2001a). To make the situation even more complicated, an organism formerly known as *Eubacterium suis* (Wegienek and Reddy, 1982) was first transferred to the genus *Actinomyces* as *Actinomyces suis* (Ludwig et al., 1992), but later to the new genus *Actinobaculum* as *Actinobaculum suis* (Lawson et al., 1997). The latter organism has been isolated from cystitis and pyelonephritis as well as metritis of pregnant sows (Soltys, 1961; Soltys and Spratling, 1957), so that it remains to be clarified which of these species are the most important swine pathogens.

Canine and feline actinomycoses have been reported comparatively frequently (Davenport et al., 1974, 1975; Georg et al., 1972; Hardie and Barsanti, 1982; Kawamura et al., 2005; McGaughey et al., 1951; Moens and Verstraeten, 1980) and include infections of the soft tissue of the jaw, as well as thoracic and abdominal cases. Tail, scrotum, epidural space, meninges and brain, vertebrae and other bones, as well as the eye or heart valves, may also be affected (Barnes and Grahn, 2007; Bestetti et al., 1977; Couto et al., 2000; Johnson et al., 1984; Junius et al., 2004; Murakami et al., 1997). Most of the actinomycotic processes encountered in dogs and cats have been caused by *Actinomyces viscosus sensu lato* (Bestetti et al., 1977; Davenport et al., 1975; Davenport et al., 1974; Donohue and Brightman, 1995; Georg et al., 1972; Hardie and Barsanti, 1982; Johnson et al., 1984; Moens and Verstraeten, 1980; Murakami et al., 1997). *Actinomyces odontolyticus* was identified as the causative agent in a dog with a subvertebral mass and quadriplegia (Edwards et al., 1988) and a case of feline pyothorax was also assumed to have been caused by this species (Thompson et al., 1992).

Several additional *Actinomyces* species may be considered specific pathogens of dogs and cats: *Actinomyces hordeovulneris* (Buchanan et al., 1984) was first isolated from pleuritis, peritonitis, visceral abscesses, septic arthritis, and recurrent localized infections of dogs in California and was found to be frequently associated with injuries caused by awns of the grass *Hordeum*. These awns, which easily penetrate skin or mucous membranes, are propelled forward through the affected tissue with any adjacent muscle contraction, leaving trails of inflammation and necrosis (Brennan and Ihrke, 1983). Infections in dogs due to *Actinomyces hordeovulneris* have also been reported from Hungary (Pelle et al., 2000) and occasionally observed in Germany (Schaal, unpublished observation). The ability of this organism to produce L-phase variants spontaneously with coincident calcium deposition (Buchanan and Scott, 1984) was believed to be related to sulfur granule formation *in vivo*. As *Actinomyces hordeovulneris* can be recovered from the gingival margin of cats (Love et al., 1990), it appears sensible to assume that the organism is introduced into tissue from the oral cavity or intestinal tract when mucous membranes are penetrated by the awns or when the animal licks or bites a wound. In addition or alternatively, the pathogen may have spread hematogenously to the necrotic focus resulting from an awn injury.

Actinomyces bowdenii (Pascual et al., 1999) is another new species that has been isolated from canine and feline clinical specimens, in particular from an abscess under the mandible of a dog, from feline pleural fluid, from a canine neck abscess, and from a pyogranuloma in a dog. All of these isolates were found to be associated with aerobically or anaerobically growing concomitant organisms such as *Pasteurella multocida*, *Prevotella* species, or *Fusobacterium* species. *Actinomyces canis* (Hoyles et al., 2000) has been recovered in mixed culture with other bacteria from the vagina and pus specimens of dogs. The two strains identified so far as *Actinomyces catuli* (Hoyles et al., 2001b) were of similar origin as was the single isolate of *Actinomyces coleocanis* (Hoyles et al., 2002a) from vaginal secretions of a cocker spaniel dog together with "*Corynebacterium genitalium*". Even in a case of mitral valve endocarditis in a labrador retriever, an *Actinomyces* species, namely *Actinomyces turicensis*, was identified as causal agent (Junius et al., 2004).

Actinomycosis-like lesions have been reported from sheep, goats, horses, deer, moose, antelope, mountain sheep, gazelles, and even from an arctic fox (Raju et al., 1986; Slack and Gerencser, 1975; Snyder et al., 1987). However, detailed information on the *Actinomyces* species etiologically involved is sparse. In one case of pyogenic granulomas found in the abdomen of a mandrill, *Actinomyces israelii* was identified as the etiologic agent using immunofluorescence (Altman and Small, 1973). *Actinomyces marimammalium* (Hoyles et al., 2001c) was isolated from two dead seals and a dead porpoise, but its pathogenic potential has not been determined yet.

Actinomyces viscosus sensu stricto ("hamster strains of *Actinomyces viscosus*") was recovered from dental plaque of hamsters with naturally occurring periodontal disease (Howell, 1953; Jordan and Keyes, 1964, 1965; Syed et al., 1981) indicating that this organism apparently contributes to the development of this disease in hamsters.

Various domestic and laboratory animals including horses, cattle, sheep, goats, pigs, dogs, rabbits, guinea pigs, rats, hamsters, and mice have been used to produce experimental infections with *Actinomyces* species (Slack and Gerencser, 1975). After intraperitoneal, intravenous, or subcutaneous injection, *Actinomyces bovis*, *Actinomyces israelii sensu lato*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, and *Actinomyces viscosus sensu lato* were all found to cause abscess formation which resembled, at least to some extent, naturally occurring actinomycotic lesions (Schaal, 1986b). However, progressive inflammatory processes rarely developed from these abscesses and the infected animals usually survived. Only certain rough strains of *Actinomyces israelii* were found to produce slowly

progressive chronic infections extending into other body areas which finally led to the animals' death (Behbehani and Jordan, 1982). Furthermore, detailed histopathological examinations showed that the actinomycotic lesions produced by *Actinomyces israelii* in mice differed considerably from those following challenge with *Actinomyces naeslundii sensu lato* or *Actinomyces viscosus sensu lato* (Behbehani et al., 1983a). These and other findings indicate that the virulence of *Actinomyces* species apparently varies between both species and individual strains, and the susceptibility of the test animals may also vary considerably (Beaman et al., 1979; Coleman and Georg, 1969; Georg et al., 1972; Georg and Coleman, 1970; Pine et al., 1960; Wolff and Israel, 1891). In addition, it has been shown that the simultaneous challenge with *Actinomyces israelii* and *Eikenella corrodens* decreased the minimal infecting dose of *Actinomyces israelii* markedly stressing the role of concomitant bacteria in the naturally occurring disease (Jordan et al., 1984). Similar results were obtained when *Actinomyces israelii* cells were packed in alginate gel particles as this led to the formation of structures comparable with sulfur granules (Sumita et al., 1998). Using an ischemic mouse thigh model for demonstration of pathogenicity, Chatterjee and Chakraborti (1989) found that *Actinomyces naeslundii sensu lato*, under these experimental conditions, exhibited an especially high degree of virulence, causing death in all test animals within 24 hours. Mice and hamsters appear to be the most suitable laboratory animals for pathogenicity studies of fermentative actinomycetes (Slack and Gerencser, 1975), although an animal model satisfactorily resembling naturally occurring actinomycoses has not been developed.

The only animal *Actinomyces* species that appear to be nonpathogenic are *Actinomyces denticolens*, *Actinomyces howellii*, *Actinomyces ruminicola*, and *Actinomyces slackii* although detailed pathogenicity studies with these organisms have not been performed (An et al., 2006; Dent and Williams, 1984b, 1984c, 1986).

Numerous animal experiments were undertaken on the ability of *Actinomyces* species to colonize teeth (Crawford and Clark, 1986; de Jong et al., 1983) and on their role in the development of caries and periodontitis. After oral inoculation, *Actinomyces naeslundii* (human strains) and *Actinomyces viscosus* (human and hamster strains) were shown to produce periodontal disease with alveolar bone loss and/or root surface caries in hamsters (Hernandez, 1985; Jordan and Keyes, 1964; Kametaka et al., 1989), as well as in conventional and gnotobiotic rats (Brecher and van Houte, 1979; Brecher et al., 1978; Burckhardt et al., 1981; Crawford et al., 1978; Firestone et al., 1987; Jordan et al., 1965; Llory et al., 1971; Shakespeare et al., 1985; Socransky et al., 1970). Similar observations were made with *Actinomyces israelii* orally implanted into gnotobiotic rats: this organism produced extensive plaque formation accompanied by root surface caries and bacterial invasion of the pulp (Behbehani et al., 1983b).

The factors of pathogenicity and/or virulence which enable *Actinomyces* species to invade tissue and to cause necrosis and abscess formation remain to be elucidated in detail. In contrast, *Actinomyces naeslundii sensu lato*, *Actinomyces viscosus sensu lato*, and possibly *Actinomyces israelii sensu lato*, and *Actinomyces odontolyticus* were shown to possess a large variety of properties which apparently contribute to the formation of dental plaque and to the development of periodontal disease, gingivitis, and caries. Adherence and coaggregation mechanisms involved in plaque formation have already been described. The same is true for certain surface components which may represent virulence antigens. In addition, *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* were found to form a food chain with *Veillonella* (Distler and Kröncke, 1981; Distler et al., 1980), to produce chemotactic effects, a polyclonal B-cell activator and a stimulus for lysosome release in polymorphonuclear phagocytes, to induce release of mediators of inflammation and immunoglobulin production, and to mark fibroblasts for immune-mediated damage (Burckhardt, 1978; Clagett et al., 1980; Engel et al., 1976; Engel et al., 1978; Mangan and Lopatin, 1981; Taichman et al., 1978; Wicken et al., 1978).

Ecology. All of the recognized *Actinomyces* species appear to occur primarily as normal inhabitants of the mucosal surfaces of man and other homoiothermic animals although this has not been proven definitely for all of them. Thus, the typical pathogenic species may be considered facultative pathogens which invade the body of their hosts endogenously and are not transmissible (exception: "punch actinomycosis" following human bites).

The oral cavity of man and animals is obviously the principal natural habitat of members of the genus *Actinomyces*. There, they colonize teeth and oral mucosal surfaces, are able to resist natural and artificial cleaning mechanisms and utilize organic compounds present in the oral cavity as nutritional sources. Furthermore, they show complex interactions with other oral microbes thereby being involved in the formation of dental plaque. Thus, dental plaque or calculus and saliva are the materials from which actinomycetes can consistently be recovered by either immunofluorescence or culture (Bergey, 1907; Emmons, 1936, 1938; Ennever et al., 1951; Howell et al., 1959; Morris, 1954; Naeslund, 1925; Rosebury et al., 1944; Slack, 1942; Slack and Gerencser, 1975; Sullivan and Goldsworthy, 1940). *Actinomyces israelii sensu lato*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, and *Actinomyces viscosus sensu lato* have all been identified in such samples since the early days of bacteriology (Batty, 1958; Collins et al., 1973; Ellen et al., 1978; Gerencser and Slack, 1969; Hill et al., 1977; Howell et al., 1959, 1962; Lentze, 1948; Naeslund, 1925; Russell and Melville, 1978; Slack, 1942; Slack et al., 1971; Snyder et al., 1967; Socransky, 1970; Sutter, 1984; Thompson and Lovestedt, 1951). Human periodontal sulci appear to be the principal habitat of *Actinomyces meyeri* (Cato et al., 1984).

Gram-stain-positive, facultative and anaerobic bacteria were reported to constitute 15–29% of the cultivable flora in saliva and on the tongue, 40% of that in dental plaque and 35% of that in the gingival crevice (Socransky and Manganiello, 1971). Actinomycetes amounted to about 40% of the cultivable organisms in plaque (Brown et al., 1986; Ellen et al., 1985; Loesche et al., 1972; Nyvad and Fejerskov, 1989). The total count of fermentative actinomycetes in human dental calculus was estimated at 1.9×10^7 cells per gram wet weight (Collins et al., 1973). For individual species, the counts were: *Actinomyces israelii sensu lato*, 6.32×10^6; *Actinomyces naeslundii sensu lato*, 5.37×10^6; *Actinomyces odontolyticus*, 0.1×10^6; *Actinomyces viscosus sensu lato*, 4.39×10^6; when no signs of inflammation were present. In patients with periodontal disease, the respective figures were: *Actinomyces israelii sensu lato*, 14.01×10^6; *Actinomyces naeslundii sensu lato*, 2.38×10^6; *Actinomyces*

odontolyticus, 1.26×10^6; *Actinomyces viscosus sensu lato*, 4.39×10^6 (Collins et al., 1973).

The numbers of actinomycetes in the oral environment may be influenced by inhibitory factors released by other bacteria (Rogers et al., 1978), by fluorides or other measures for preventing caries (Beighton and McDougall, 1977; Johansen et al., 1997; Phan et al., 2000), or by the eating habits of the host (Minah et al., 1985; Pfister et al., 1984). Furthermore, actinomycete bacteriophages with high host cell specificity may play an active role in the oral microbial ecology (Tylenda et al., 1985a). In any case, the qualitative and quantitative composition of the oral microflora differs from the saliva (in the planktonic state) to the mucosal surface (in the biofilm state), from the saliva to the tooth surface (in the biofilm state), and even from tooth to tooth and at different sites on one single tooth.

Recent studies on the oral colonization with *Actinomyces* species in healthy infants between the 2nd and 24th month of their life-time have provided insight into the composition of the actinomycete oral flora in relation to the early age period (Sarkonen et al., 2000). Within the first two years, the relative frequency of the total actinomycete flora increased from 31% to 97%. *Actinomyces odontolyticus* appeared to be the most prominent colonizer at all of the sampling occasions (after 2, 6, 12, 18, and 24 months of age). *Actinomyces naeslundii sensu lato* was also commonly encountered but not before the age of one year, as this species has been regarded one of the pioneer colonizers of tooth surfaces (Kolenbrander et al., 1999). *Actinomyces graevenitzii* was also rather regularly identified in the mouths of children (Sarkonen et al., 2000) as were *Actinomyces georgiae*, *Actinomyces gerencseriae*, *Actinomyces israelii*, and *Actinomyces viscosus sensu lato* in the oral cavity of children and in gingival crevices of periodontally healthy adults (Cato et al., 1984; Johnson et al., 1990).

Actinomyces israelii sensu lato, *Actinomyces naeslundii sensu lato* and possibly other *Actinomyces* species have also been demonstrated in human tonsils (Blank and Georg, 1968; Emmons, 1938; Garcia Ramos et al., 1984; Grüner, 1969; Hotchi and Schwarz, 1972). Occasionally, *Actinomyces viscosus sensu lato* and other *Actinomyces* species may also be recovered from the uninfected conjunctiva and/or cornea (Jones and Robinson, 1977; Schaal and Beaman, 1984).

Information on the occurrence of *Actinomyces* species as normal inhabitants of the human intestinal tract is very scarce although cases of abdominal actinomycoses that developed endogenously after bowel surgery, appendix perforation, or injuries of the intestine suggest that these organisms might form a small but significant component of the intestinal flora. The observations of Minsker and Moskovskaya (1979) who recovered *Actinomyces israelii* from 60.3% of diseased appendices examined support this view. The same is true for the findings of Fritsche ((1964b) and unpublished observations) who was able to isolate *Actinomyces israelii* from stool specimens of healthy individuals when using strong selective measures. Noack-Loebel and coworkers (1983), when comparing the composition of the fecal flora in two groups of children of primary school age, reported that the numbers of fermentative actinomycetes were significantly influenced by individual dietary habits: Children with a lacto-ovo-vegetarian diet presented with increased numbers of fermentative actinomycetes along with increased *Bifidobacterium* and *Enterobacteriaceae* counts as compared to school children with normal, *ad libitum* diets. Furthermore, studies on the composition of the microflora in duodenal and jejunal fluids suggest that *Actinomyces* species frequently form an important component of the cultivable flora of the upper intestinal tract (Bernhardt and Knoke, 1984; Justesen et al., 1984a; Justesen et al., 1984b). However, as the actinomycetes occurred together with other oral bacteria, it remains to be determined whether they represent true indigenous microbiota of the upper small intestine or simply "washed-down" oral organisms.

Previously, the vagina, the cervical canal, or the *cavum uteri* were not considered natural habitats of fermentative actinomycetes (Hanf and Hanf, 1955). Also in more recent studies, it was often not possible to demonstrate these organisms in healthy women who did not use IUCDs (Jones et al., 1983). However, other reports indicate that at least *Actinomyces israelii* and *Propionibacterium propionicum* may occur in the female genital tract independently of the use of IUCDs. When IUCDs were not used, the percentage of positive specimens ranged from 3% for *Actinomyces israelii sensu lato* (Persson et al., 1983) and 19% for *Actinomyces* species in general (Grice and Hafiz, 1983) to more than 70% for *Actinomyces israelii sensu lato* alone (Persson and Holmberg, 1984). In women wearing IUCDs or vaginal pessaries, it is usually easier to demonstrate these organisms either in cervicovaginal secretions or on the IUCD and, in particular, on its thread reaching from the *cavum uteri* to the vagina (Pine et al., 1985).

Nevertheless, the isolation or microscopic demonstration rates of actinomycetes in materials from the female genital tract varied widely between 0% (Schiffer et al., 1978) to more than 80% (Duguid et al., 1982; Eibach et al., 1989, 1992; Grice and Hafiz, 1983; Gupta et al., 1978; Gupta et al., 1976; Hager et al., 1979; Jarvis, 1985; Persson et al., 1983; Pine et al., 1981; Schaal and Pulverer, 1984; Traynor et al., 1981; Valicenti et al., 1982). These differing results indicate that sensitivity and specificity of the detection methods used are apparently not comparable and that, in addition, there might also exist regional, ethnic, social, or even religious differences. Furthermore, it remains to be clarified whether (as with oral cavity actinomycetes) genital actinomycetes also occur in association with amoebae (Arroyo and Quinn, 1989).

Apart from *Actinomyces israelii* and *Propionibacterium propionicum*, several additional *Actinomyces* species have been identified in specimens from the female genital tract. These included *Actinomyces cardiffensis*, *Actinomyces gerencseriae*, *Actinomyces meyeri*, *Actinomyces naeslundii sensu lato*, *Actinomyces odontolyticus*, and *Actinomyces viscosus sensu lato* (Eibach et al., 1989, 1992; Hall et al., 2002; Mitchell and Crow, 1984; Schaal and Pulverer, 1984; Schaal and Lee, 1992). Occasionally, two different *Actinomyces* species such as *Actinomyces israelii* plus *Actinomyces oris* or *Actinomyces israelii* plus *Actinomyces odontolyticus* may be isolated from a single genital specimen (Schaal, unpublished observation).

The occurrence of *Actinomyces* species in healthy animals is less well documented. Nevertheless, *Actinomyces viscosus* has been isolated from subgingival plaque of hamsters and from cervical plaque of rats (Bellack and Jordan, 1972; Howell, 1963; Howell and Jordan, 1963; Jordan and Keyes, 1964, 1965). Beighton (1985) in a study on the microbial colonization of the mouths of neonatal monkeys (*Macaca fascicularis*) found that *Actinomyces naeslundii sensu lato* and, to a lesser extent, *Actinomyces viscosus sensu lato* was established in the dental plaque of

these animals during the period of breast-feeding, suggesting that these organisms belong to the basic plaque flora which is altered by diet as the animals mature. Similarly, *Actinomyces denticolens*, *Actinomyces howellii*, and *Actinomyces slackii* were recovered from the dental plaque of cattle (Dent and Williams, 1984b, 1984c, 1986) as were *Actinomyces denticolens*, *Actinomyces hordeovulneris*, and *Actinomyces viscosus* from the gingival margin of healthy cats (Love et al., 1990). The natural habitat of the "vaginal" biovar of *Actinomyces hyovaginalis* was assumed to be the porcine genital tract (Collins et al., 1993); members of the "general" biovar of the species were recovered from many different body sites including the genital tract, but their natural habitat remains to be determined (Storms et al., 2002). It also remains to be definitely demonstrated to which biovar the isolates of *Actinomyces hyovaginalis* belong: these strains were recovered from a large number of tonsils of piglets before and after weaning (Baele et al., 2001). *Actinomyces ruminicola* originated from cattle rumen (An et al., 2006). Interestingly, however, Dent and Williams (1984c), in their study on the microflora of the bovine dental plaque, were not able to identify any *Actinomyces*-like isolate from healthy cattle as *Actinomyces bovis* so that the normal habitat of this species still awaits clarification. The same is true for essentially all of the other recently described animal *Actinomyces* species that were as yet solely derived from various clinical conditions.

Enrichment and isolation procedures

Although *Actinomyces* species are rather fastidious as far as the composition of the growth medium is concerned, several complex general purpose media have been found to be useful for isolating these organisms from clinical specimens, the oral cavity of man and animals, or from other natural habitats. These media include fluid thioglycolate broth (THIO) possibly supplemented with 0.1–0.2% (w/v) sterile rabbit serum, Todd–Hewitt broth supplemented with rabbit serum, peptone-yeast extract-glucose broth or agar (PYGB, PYGA), brain heart infusion broth or agar (BHIB, BHIA), cooked-meat medium, trypticase soy broth (TSB) or agar (TSA), heart infusion agar or TSA with 5% (w/v) defibrinated rabbit, sheep or horse blood, Columbia agar with 5% (w/v) defibrinated sheep or horse blood, brucella agar with or without addition of defibrinated blood, Schaedler broth or agar, or Fastidious Anaerobe Agar (Neogen, Lansing, MI, USA) (Schaal, 1986b; Schaal and Pulverer, 1981; Schaal et al., 2006; Slack and Gerencser, 1975).

For culturing *Actinomyces meyeri*, addition of vitamin K_1 to the medium (PYGB or PYGA) is obligatory and growth of this species is greatly stimulated by 0.02% (w/v) Tween 80 and a fermentable carbohydrate (Cato et al., 1984). Similarly, *Actinomyces hordeovulneris* requires addition of 10–20% (v/v) fetal bovine serum to the medium for adequate growth (Buchanan et al., 1984). *Actinomyces ruminicola* is best grown in PYGB or PYGA supplemented with 15% rumen fluid. Furthermore, this organism requires elevated growth temperatures between 39 and 46°C (An et al., 2006). All of the other *Actinomyces* species grow well at 36±1°C (Schaal, 1986b; Schaal et al., 2006; Slack and Gerencser, 1975).

For diagnosing actinomycete infections, which usually contain numerous concomitant other bacteria, as for detecting actinomycetes in dental plaque or similar materials, broth enrichment media are less suitable because the slowly growing actinomycetes are mostly overgrown by the concomitant or indigenous flora. Consequently, they are easily overlooked or their growth is even completely suppressed. The general purpose agar media mentioned above, especially when supplemented with defibrinated blood, may pose problems in that characteristic filamentous colonies (of the typical human pathogens) may not develop or may not be discernible because abundant growth of additional microbes often masks actinomycete growth (Schaal, 1986b; Schaal et al., 2006). Furthermore, non-transparency of the medium due to blood cells hampers the recognition of filamentous growth. The detection of the classical pathogenic species can be improved by employing complex semisynthetic media such as those of Pine and Watson (1959) or Heinrich and Korth (1967) (CC-medium: see footnote †). The latter media promote the development of characteristic filamentous micro- and macrocolonies and reduce growth of the concomitant flora. In addition, CC-medium plates facilitate the recognition of spider-like colonies when viewed under a microscope at low magnifications (80–100×) (Figures 28–32). If a long-distance objective is used, cultures can be examined through the transparent medium without opening sealed plates such as Fortner plates (see below) (Lentze, 1938a).

Although Tarozzi broth (see footnote ‡) is in principle an enrichment medium, characteristic snow ball or cotton pad-like colonies of pathogenic actinomycetes can often be seen on the surface of the liver piece (Figure 56) especially when they are present together with *Aggregatibacter actinomycetemcomitans*. These colonies can easily be picked for subculture using a Pasteur pipette. The above procedures are particularly useful inasmuch as studies on the selective isolation of *Actinomyces* species from pus specimens have rarely been performed. Columbia blood agar (with defibrinated horse blood) supplemented with mupirocin (128 mg/l) and metronidazole (2.5 mg/l) (MMBA) was reported to greatly increase the percentage of *Actinomyces* isolates (up to 71% of specimens) from dentofacial infections as well as from IUCDs (Lewis et al., 1995). However, further studies are needed to decide whether these additional actinomycete isolates are of etiological relevance because they included relatively large proportions of *Actinomyces meyeri*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, and *Actinomyces viscosus* which are not known as frequent causative agents of cervicofacial actinomycoses.

Selective principles have, however, been used successfully for isolating and enumerating actinomycetes from dental plaque or saliva. The four different selective media devised for this purpose differ to some extent in their selectivity against other oral microbes and in their inhibitory activity to individual *Actinomyces* species. Ellen and Balcerzak-Raczkowski (1975) described a partially selective medium for *Actinomyces naeslundii sensu lato* (human strains) and *Actinomyces viscosus sensu lato* (CNAC-20 medium*). After inoculation, the medium is incubated at 36±1°C in 90% air and 10% CO_2 in order to encourage growth of *Actinomyces johnsonii*, *Actinomyces naeslundii*, and *Actinomyces oris* while inhibiting the more anaerobic actinomycetes and other Gram-stain-

*CNAC-20 Medium (Ellen and Balcerzak-Raczkowski, 1977): I. Basal culture medium: Columbia CNA agar base (Difco). II. Preparation of the selective medium: Add $3CdSO_4\ 8H_2O$ to the basal medium to give a final concentration of 20 mg/ml. Autoclave. Incubate plates containing the medium at 36±1°C in 90% air and 10% CO_2.

positive oral anaerobes. The medium of Beighton and Colman* (1976) was developed for the selective isolation of oral actinomycetes in general, while that of Kornman and Loesche (1978) (GMC Medium†) was designed for the preferential detection of *Actinomyces naeslundii* and *Actinomyces viscosus (Actinomyces oris* and *Actinomyces johnsonii*). The latter medium was reported to allow 98% recovery of *Actinomyces viscosus sensu lato* (*Actinomyces oris* and *Actinomyces johnsonii*) and 73% recovery of *Actinomyces naeslundii sensu lato* while suppressing 76% of the total count of other oral organisms. *Propionibacterium propionicum* also grew quite well on this medium whereas *Actinomyces israelii sensu lato* and *Actinomyces odontolyticus* were inhibited (Kornman and Loesche, 1978). Zylber and Jordan (1982) described a medium for the detection and enumeration of *Actinomyces naeslundii sensu lato* and *Actinomyces viscosus sensu lato* (CFAT medium‡) which contains a complex mixture of antimicrobial substances. This medium gave considerably higher counts for *Actinomyces naeslundii* and *Actinomyces viscosus* than the FC medium and the CNAC-20 medium, respectively. The major interfering organisms on this medium were *Aerococcus* and *Rothia* species, whereas FC and CNAC-20 media were less selective and supported growth of significant numbers of other oral microbes (1982).

A different means of selective isolation of fermentative actinomycetes, especially *Actinomyces israelii*, from heavily contaminated materials such as stool specimens has been described by Fritsche** (1964b). This method utilizes the inactivating effect of toluene on Gram-stain-negative bacteria and, although the colony morphology of actinomycetes may be altered upon primary isolation, it was found to be very useful for separating *Actinomyces israelii* from contaminating *Enterobacteriaceae*.

Occasionally, commercial disks for antibiotic susceptibility testing can aid in obtaining pure *Actinomyces* subcultures. Depending on the contaminating organisms, disks containing metronidazole, colistin, or nalidixic acid in common concentrations may be employed. From their inhibition zones, actinomycete colonies can often be picked easily and transferred to another plate.

To avoid loss of viability of actinomycetes by oxygen contact, clinical samples, as well as samples for ecological studies, should be inoculated onto suitable culture media as soon as possible. Alternatively, reduced transport media should be used. For clinical specimens, the Stuart transport medium or its commercial modifications (e.g. Port-A-Cul, Becton Dickinson) has proved satisfactory (Loesche et al., 1972; Syed and Loesche, 1972). For ecological studies, the reduced transport fluid (RTF††) of Syed and Loesche (1972) may be more appropriate. This medium can also be used for sonic or mechanical dispersal of more solid materials.

Anaerobic growth conditions may be obtained by using a Torbal anaerobic jar with a gas mixture of N_2-H_2-CO_2 (80:10:10%), a GasPak jar (Becton Dickinson) with a H_2-CO_2-generating envelope and an active catalyst or an anaerobic chamber or a glove box with appropriate gas mixtures. Use of pre-reduced, anaerobically sterilized media or the roll-tube technique are usually not necessary. The capnophilic members of the genus may be grown in a candle jar or in a GasPak jar with a CO_2-generating unit. For routine use in the diagnostic laboratory, Fortner's method‡‡ (Fortner, 1928, 1929) has proved especially useful and reliable, because cultures can be checked for growth without disturbing the gaseous conditions and the semi-anaerobic atmosphere of this technique allows growth of essentially all of the pathogenic *Actinomyces* species including the more aerophilic ones (Schaal and Pulverer, 1981).

All *Actinomyces* cultures apart from those of *Actinomyces ruminicola* are incubated at 35–37°C and should be checked at 2, 4, 7, and 14 d for growth of characteristic micro- or macrocolonies, respectively (Schaal, 1986b; Schaal et al., 2006). Optimum growth temperature of *Actinomyces ruminicola* is 46°C (An et al., 2006).

Maintenance procedures

Actinomyces species may cause problems in continuous subculture, especially when the growth medium contains significant

*Selective medium for oral actinomycetes (Beighton and Colman, 1976): I. Basal culture medium (BYS medium): Brain heart infusion broth, 3.7 g; yeast extract powder, 0.5 g; polyvinylpyrrolidone, 1.0 g; cysteine-HCl, 0.1 g; agar, 1.5 g. Add these ingredients to 100 ml of distilled water and autoclave for 15 min at 121°C. Cool to 45°C and supplement with 5 ml of sterile horse serum. II. Selective enrichment medium (FC medium), containing per 100 ml BYS medium: NaF solution (25 mg/ml), 1.0 ml; colistin sulfate solution (1 mg/ml), 0.5 ml. The inhibitor solutions are sterilized separately by autoclaving at 121°C for 15 min before they are added to the BYS medium.

†Selective GMC medium for (human) *Actinomyces viscosus* and *Actinomyces naeslun*dii strains (Kornman and Loesche, 1978): I. Basal medium: The enriched gelatin agar of Syed (1976) is recommended, but other complex media may yield similar results. II. Selective medium, containing per liter basal medium: cadmium sulfate ($3CdSO_4$ $8H_2O$), 20 mg; metronidazole, 10 mg. Autoclave cadmium sulfate together with the basal medium. Cool to 45–50°C and add a filter sterilized solution of metronidazole aseptically.

‡Selective medium for detection and enumeration of *Actinomyces viscosus* and *Actinomyces naeslundii* (CFAT medium) (Zylber and Jordan, 1982): Composition per liter: trypticase soy broth (Becton Dickinson), 30.0 g; glucose, 5.0 g; agar, 15.0 g; cadmium sulfate ($3CdSO_4$ $8H_2O$), 13.0 g; sodium fluoride (NaF), 80.0 mg; neutral acriflavin, 1.2 mg; potassium tellurite, 2.5 mg; basic fuchsin, 0.25 mg; defibrinated sheep blood, 50 ml. Adjust the final pH to 7.3.

**Selective isolation of Actinomyces israelii (Fritsche, 1964b): The specimen is suspended and dispersed in a suitable transport fluid (e.g., reduced transport fluid of Syed and Loesche (1972) or in thioglycolate broth). Add 1 ml of the suspension thus obtained to 1 ml of toluene in a screw-cap tube. Agitate the tube on a mechanical shaker (high speed) for 20–25 min. Remove the watery suspension at the bottom of the tube carefully with a capillary pipette and add it to 10 ml of the same transport fluid or broth. Remove remaining droplets of toluene on the surface of the fluid with a Bunsen flame. Centrifuge so that the *Actinomyces* cells can settle and streak the sediment onto non-selective agar media.

††Reduced transport fluid (RTF) (Syed and Loesche, 1972): I. Stock mineral salts solution No. 1, containing: K_2HPO_4, 0.6% (w/v). II. Stock mineral salts solution No. 2, containing: NaCl, 1.2% (w/v), $(NH_4)_2SO_4$, 1.2% (w/v), KH_2PO_4, 0.6% (w/v), $MgSO_4$, 0.25% (w/v). III. Final transport medium, containing per liter: Stock solution No. 1, 75 ml; stock solution No. 2, 75 ml; 0.1 M ethylenediaminetetraacetate solution, 10 ml; 8% Na_2CO_3 solution, 5 ml; 1% dithiothreitol solution (freshly prepared), 20 ml; 0.1% resazurin solution (optional), 1 ml; distilled water, 814 ml. Sterilize by membrane filtration (pore size, 0.22 µm). Dispense into 16 × 125 mm screw-cap tubes (dilution tubes) and 18 × 150 mm test tubes (sample-collection tubes). The pH should be 8±0.2 without adjustment, and it decreases to pH 7 in 48 h in the anaerobic glove box atmosphere (85% N_2, 10% H_2, 5% CO_2).

‡‡Fortner's method for obtaining (semi-)anaerobic growth conditions (Fortner, 1928): Use only agar media, preferably transparent ones, in glass Petri dishes! Inoculate one-half to two-thirds of the agar surface with the material to be examined or with the strain to be subcultured. Inoculate the remaining agar surface heavily with a *Serratia marcescens* culture using a spatula. Place the dish upside down upon a glass sheet of appropriate size. Fix and seal the dish with plasticine to make the system airtight. Incubate at 36±1°C for up to 14 days and examine for microbial growth and especially filamentous colonies every 2 days using either a hand lens or a microscope equipped with a long-distance 10× objective in transmitted light without opening the plate. (Leakage in the plasticine seal which may occur when the plasticine is too brittle or the base glass sheet is damp, can easily be detected because pigment-producing strains of *Serratia marcescens* form nonpigmented growth under shortage of oxygen, but become red when the system is not completely airtight.)

amounts of fermentable carbohydrates which rapidly lead to toxic low pH values (Schaal et al., 2006). In addition, cultures of these organisms are liable to contamination with propionibacteria which are often difficult to recognize.

Cultures in routine use may be maintained by weekly transfer in thioglycolate broth containing 0.2% (v/v) rabbit serum or by monthly transfer on Fortner plates containing CC-medium or in Tarozzi broth. For longer preservation (up to 1 year) and long-term storage (up to 10 years or longer) freezing or lyophilization is recommended (Schaal, 1986a, 1986b; Schaal et al., 2006; Slack and Gerencser, 1975).

For freezing, 3–5 ml brain heart infusion broth in screw-capped tubes are inoculated with 0.1 ml of a fresh broth culture or a dense suspension of the organism in BHIB prepared from a 3–7 d-old agar culture. The inoculated broth is incubated at 36±1°C (*Actinomyces ruminicola*: 46°C) for 3–5 d under appropriate gaseous conditions (in air, usually with added CO_2, or in an anaerobic jar or chamber) with the caps loosened. As soon as good growth is obtained, the caps are tightened and the tubes are placed in a freezer at −70°C.

For freeze-drying, the sediment of broth cultures or – preferably – biomass scraped from agar plates or dialysis membranes are suspended in sterilized skim milk or lyophilization medium* and lyophilized using standard techniques (Schaal, 1986a, 1986b; Schaal et al., 2006; Slack and Gerencser, 1975). Lyophilized *Actinomyces* cultures have been reported to remain viable for 10 years when stored at room temperature (Slack and Gerencser, 1975). Most lyophilisates can even be revived after 20–30 years of storage at room temperature (Schaal et al., 2006). Frozen broth cultures will survive for at least 1 year.

Procedures for testing of special characters

Pus from actinomycotic abscesses or the purulent discharge from sinus tracts occasionally contain large amounts of sulfur granules which give these exudates the macroscopic appearance of semolina soup (Lentze, 1969; Schaal, 1984; Schaal et al., 2006b). More often, however, sulfur granules are not immediately apparent so that the laboratory personnel have specifically to search for hard, yellowish to brownish to reddish particles of up to 1 mm in diameter in the purulent discharge. As pus specimens may contain other structures that resemble sulfur granules in terms of size, color, and texture (e.g., granules of actinomycetomas), the nature of suspected sulfur granules has to be confirmed by subsequent microscopic examination. For this purpose, the granule is placed in the middle of a microscopic glass slide, one drop of 1% methylene blue solution is added, and the slide is covered with a cover glass. After having gently pressed down the cover slip, the preparation is viewed under the microscope in transmitted light at about 100× magnification. Under these conditions, the sulfur granules appear as cauliflower-like structures which, because of the reducing capacity, retain an unstained center whereas surrounding leukocytes and peripheral hyphae take up the blue color of the dye. After slightly harder pressing onto the coverslip, sulfur granules usually disintegrate into spherical or partially spherical elements that represent actinomycete colonies formed *in vivo* (Schaal, 1992a; Schaal et al., 2006).

For detailed microscopic examination at high magnifications, the particles are crushed between two slides and the smears thus obtained are Gram-stained and viewed at 800–1000× magnification. Stained smears of sulfur granules typically show nests of Gram-stain-positive, branched, unevenly curved and irregularly stained filaments and rods. In addition, various other Gram-stain-positive and Gram-stain-negative bacteria together with leukocytes can be seen indicating the presence of the concomitant flora.

The morphology of *Actinomyces* microcolonies is demonstrated most easily on BHIA or CC-medium plates that have been incubated for 18–24 h. The colonies may be observed directly on the medium (Erikson, 1940; Lentze, 1938a) within the plate, or small sections of agar may be removed and placed on a glass slide to facilitate the use of the microscope. Magnifications of 100–400× are usually satisfactory (Slack and Gerencser, 1975). If higher magnification is required for the detailed study of young microcolonies (oil immersion), a slide culture technique† together with lactophenol cotton-blue staining of the microbes may be more appropriate. Mature colonies are observed on BHIA or blood agar plates after 5–14 d of incubation using a hand lens or a dissecting microscope.

Tests for oxygen requirements are performed according to Slack and Gerencser‡ (1975). The analysis of the acid end products resulting from the fermentative carbohydrate metabolism of *Actinomyces* species is usually performed using gas-liquid chromatography (GLC) according to the procedures described in the VPI Anaerobe Laboratory Manual (Holdeman et al.,

*Lyophilization medium for long-term storage of Actinomyces species (Schaal, 1986a; Schaal et al., 2006): Brain heart infusion broth, 1 part; horse or fetal bovine serum, 1 part; sucrose to give a final concentration of 7% (w/v) in the whole mixture.

†Slide culture technique for the microscopic observation of filamentous actinomycete microcolonies (Schaal, 1986b; Schaal et al., 2006): I. Preparation of slide cultures: Cover glass slides with a thin layer of BHIA by briefly immersing one surface of the slide in melted BHIA at about 50°C. For solidification of the agar, transfer the slide immediately to a sterile Petri dish containing a sheet of filter paper moistened with sterile water. Perform all of the necessary manipulations under strict aseptic conditions (a clean bench). II. Culture: Inoculate the agar-coated slides with the strain to be examined using a very thin, freshly drawn glass filament. Incubate the slide cultures inside their moist dishes in an anaerobic or CO_2-enriched atmosphere. III. Microscopy: After 5-10-20 h incubation, the agar films are air-dried 10–15 min. Then, 1–3 drops of lactophenol-cotton blue mounting fluid (formula see below) are placed in the center of the agar layer and covered with a cover glass. View under the microscope using phase-contrast equipment and objectives between 50× and 100× magnification. IV. Lactophenol-cotton blue mounting fluid (Hendrickson, 1985): Phenol crystals, 20 g; lactic acid, 20 ml; glycerol, 40 ml; distilled water, 20 ml. Dissolve the ingredients by heating the flask in a hot water bath. Add 0.05 g of cotton blue (Poirier blue).

‡Tests for oxygen requirements (Slack and Gerencser, 1975): I. Agar slant method: Suspend cells obtained from about 3-day-old cultures in 0.85% saline and adjust the suspension to a density matching the MacFarland 3 standard. Inoculate eight BHIA slants in cotton-plugged tubes with the suspension using a capillary pipette. Incubate the slants, in duplicate, under the following conditions: 1. For aerobic growth, place 2 slants with the original cotton plugs directly in the incubator. 2. For aerobic conditions with added CO_2, clip off the cotton plugs of two tubes and push the remaining parts into the tube to just above the slant. Place small pieces of absorbent cotton on top of the plugs, add 5 drops of 10% Na_2CO_3 and 5 drops of 1 M KH_2PO_4 to each tube and close it immediately with a rubber stopper. 3. For anaerobic conditions with added CO_2, tubes are prepared as under 2. Then, add 5 drops of 10% Na_2CO_3 and 5 drops of pyrogallol solution (100 g pyrogallic acid in 150 ml of distilled water) to the absorbent cotton. 4. For anaerobic conditions without CO_2, add 5 drops of 10% KOH and 5 drops of pyrogallol solution to the properly prepared tubes (see 2). Record results after 3 and 7 days of incubation. If the growth in two corresponding tubes does not seem equal, the test has to be repeated. II. Agar deep method: Inoculate melted and cooled agar medium, while still liquid, with a suspension of the test organism using a capillary pipette. Push the tip of the pipette to the bottom of the tube and then withdraw slowly while expelling a drop of inoculum. Gently mix the agar by rotating the tube and allow the agar to solidify in an upright position. Read the results after 3 and 7 days of incubation by measuring the distance in millimeters between the surface and the zone of maximum growth.

1977), but more modern techniques such as high performance liquid chromatography (HPLC) may also be applied.

Comparatively simple modifications of several chemotaxonomic procedures have been developed that are easily applicable for identification purposes under diagnostic routine conditions (Alshamaony et al., 1977; Becker et al., 1964; Schaal, 1985b). This is especially true for the demonstration of diaminopimelic acid (A_2pm) or certain sugars in whole-cell hydrolysates, for the analysis of long-chain fatty acids and mycolic acids in whole-cell methanolysates, and for the determination of cytoplasmic polypeptide patterns. The former procedures have been greatly improved and facilitated by using commercially available cellulose-coated plastic sheets (Merck 5577) or silica gel-coated aluminum sheets (Merck 5554) for thin-layer chromatography (Kutzner, 1981; Schaal, 1985b, 1992b).

A prerequisite for the successful use of these techniques is the production of sufficient amounts of biomass that should not contain larger quantities of contaminating material from the culture media. Although this requirement is readily fulfilled by using carefully washed cell mass from fluid cultures, broth cultures of fermentative actinomycetes are particularly prone to microbial contamination. The latter is more easily controlled when the organisms are grown on solid media. However, the substrate mycelium of certain *Actinomyces* species may be difficult to remove from agar media so that special precautions have to be taken to secure cell mass without contaminating material from the medium. A suitable method for preparing biomass* of actinomycetes from agar cultures has been described by Schaal (1985b).

The demonstration of A_2pm in whole-cell hydrolysates can be achieved comparatively easily following the procedure of Schaal (1985b). The same is true for the determination of sugar patterns in whole-cell hydrolysates and the demonstration of mycolic acids. Analyses for the presence of A_2pm and/or mycolic acids are useful for differentiating *Propionibacterium propionicum*, *Corynebacterium matruchotii*, and other corynebacteria from members of the family *Actinomycetaceae*, while sugar patterns are helpful in differentiating *Actinomyces* species from each other. The analysis of long-chain fatty acids, isoprenoid quinones, and whole-cell protein patterns can be performed using the methods described in the literature (Collins and Jones, 1981; Dent and Williams, 1985; Jackman, 1985; Kroppenstedt, 1985; Mauff et al., 1981).

Whole-cell protein patterns have been widely used to demonstrate differences or relatedness between different collections of otherwise similar strains (Collins et al., 2000; Dent and Williams, 1985; Hoyles et al., 2000; Pascual Ramos et al., 1997a), thus possibly avoiding more laborious DNA–DNA hybridization experiments. Cell-free, more or less purified soluble protein fractions may be obtained by disintegrating bacterial cell suspension in a Mickle shaker (Mickle Engineering Ltd., Gomshall, UK) using grade 12 glass beads for 1.5 h or in a "French pressure cell" at 2200 p.s.i. and subsequent centrifugation in two steps at 20,000 to 150,000 g for 15 min and 1 h (Dent and Williams, 1985; Mauff et al., 1981). The cell-free extracts are then electrophoresed in 10% polyacrylamide-sodium dodecyl sulfate (SDS) gels as described by Swindlehurst et al. (1977). A comprehensive description of the methods useful for producing electrophoretic whole-organism protein fingerprints, including densitometric analysis and numerical analysis of the normalized protein profiles, has been published by Pot et al. (1994). Alternatively, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) may be applied directly to packed *Actinomyces* cells incubated with an equal volume of a 6.4 M urea solution (McCormick et al., 1985). The patterns thus obtained consist of many more bands than those derived from cell-free extracts, but they appear to be reproducible and well suited for classification, identification, or typing purposes.

The catalase test when applied to fermentative actinomycetes is best performed by flooding aerobic growth on slants with 3% H_2O_2 and looking for active production of gas bubbles. Anaerobic cultures must be exposed to air for 30 min before testing. The presence of cytochrome oxidase may be demonstrated by the method of Deibel and Evans (1960).

The results of the other biochemical and physiological tests listed in Table 4, Table 5, Table 7, and Table 9 may be considerably influenced by the media and methods used (Scharfen, 1973; Schofield and Schaal, 1979a; Slack and Gerencser, 1975). The data compiled in the diagnostic and descriptive tables were chiefly derived from the techniques described by Slack and Gerencser (1975) and Schofield and Schaal (1979a, 1979b, 1980, 1981), as far as the species described before 1984 are concerned. The physiological characters of all of the other *Actinomyces* species described since 1984 were derived from the original descriptions of these species and, thus, based upon the methods reported in the respective publications.

The traditional procedure for testing acid production from carbon compounds (fermentation tests), as described by Slack and Gerencser (1975), is based on thioglycolate broth without glucose or indicator supplemented with glucose-free yeast extract (0.2%, w/v) and bromocresol purple (1% aqueous solution) added in 2-ml amounts to 1 liter of the medium. To this medium, low molecular-weight carbohydrates (mono- and disaccharides) are added to give final concentrations of 1% and other compounds are used at a concentration of 0.5%.

These and similar fluid media, when used in amounts of 1 ml or more, do not always yield satisfactory and reproducible results especially when highly filamentous strains are tested as was shown in several numerical taxonomic studies (Holmberg and Hallander, 1973; Holmberg and Nord, 1975; Melville, 1965). These problems are obviously due to the inadequacy of the inoculum size and growth rate of the organisms compared to the volume of the substrate-containing medium. In contrast, the results obtained from miniaturized test procedures (Buchanan et al., 1984; Schofield and Schaal, 1980; Schofield and Schaal, 1979a, 1979b, 1980, 1981) indicate that these modifications of the traditional physiological tests are much more suitable for testing fermentative actinomycetes. However, it has also been

*Preparation of biomass from fermentative actinomycetes for chemotaxonomic tests (Schaal, 1985b): I. Media: BHIB is usually satisfactory, but other media may also be used. II. Membrane culture technique: Place autoclaved sheets of dialysis tubing on top of the agar surface of BHIA plates and inoculate them with a heavy suspension of the test strain. Incubate the plates under suitable conditions (aerobically, under increased CO_2 tension, or anaerobically), until good growth is obtained. III. Preparation of cell mass: Remove the sheets of dialysis tubing with the bacterial growth on top with sterile forceps and transfer them to Erlenmeyer flasks containing either distilled water or saline and a few glass beads (~5 mm in diameter). Inactivate the organism either by adding formaldehyde or by heating the flask in a water bath at 75°C for 45 min. Wash growth off the sheets by shaking the flasks on a rotary shaker at 200-250 rpm and collect the cell mass by centrifugation. Wash the sediment in two changes of distilled water. Dry the cells by lyophilization (amino acid and sugar analyses may also be carried out on cells dried overnight in absolute ethanol).

TABLE 3. Characteristics differentiating the genus *Actinomyces* from other genera of the family *Actinomycetaceae* and morphologically related, fermentative organisms[a,b]

shown that among the various miniaturized commercial systems, only the Minitek differentiation system (Becton Dickinson) is equally well applicable to all members of the genus *Actinomyces* (Schofield and Schaal, 1979b). As the Minitek system is no longer available on the market, a home-made modification* of this system can be used. A slightly modified procedure allows the reliable assessment of nitrate and nitrite reduction as well as of urease and arginine dihydrolase activities† (Schofield and Schaal, 1980, 1981). The agar plate method of Phillips (1976) has only sporadically been used for testing fermentation reactions of fermentative actinomycetes (Hall et al., 2005) so that its suitability remains to be proven.

Tests for enzymic activities detectable by means of chromogenic or fluorogenic substrates were shown to possess differential power when applied to classification and identification of fermentative actinomycetes (Brander and Jousimies-Somer, 1992; Casin et al., 1984; Kilian, 1978; Maiden et al., 1996; Sarkonen et al., 2001; Schofield and Schaal, 1981), but they were also found to be difficult to standardize because many of the enzymes which might be detected in this way are inducible so that the test results highly depend on the composition of the growth medium used for preparation of the inoculum.

Various commercial test systems which are based upon such enzyme tests completely or in part, have been used for the characterization and identification of *Actinomyces* species, in particular with the recently described species. These include the API ZYM, RapID ANA II, API 20 anaerobes, API 20 Strep, API Rapid ID 32 Strep, API Coryne, API (rapid) Coryne (bioMérieux), and Rosco Diagnostic Tablets (Rosco, Taastrup, Denmark) systems. A test based on 4-methylumbelliferyl (4-UM) derivatives of various substrates has also been applied successfully to the phenotypic identification of actinomycetes (Sarkonen et al., 2001; Whiley et al., 1990). Automated systems such as the Vitek System (bioMérieux) have rarely been used (Woo et al., 2003) and their performance for identifying *Actinomyces* species was generally found to be unsatisfactory (Schaal, unpublished observation).

Miniaturized multitest systems such as the API 20 anaerobes (Casin et al., 1984), API 20 Strep (Morrison and Tillotson, 1988), API Rapid ID 32 Strep (Nikolaitchouk et al., 2000), API Coryne (Hoyles et al., 2001a, 2001b, 2001c) and API (rapid) Coryne (Funke et al., 1997b) systems contain carbohydrate fermentation reactions in addition to enzyme tests or they consist exclusively of fermentation reactions such as the API 50 CH system (bioMérieux). When applied to the characterization and identification of fermentative actinomycetes, the reliability and reproducibility of the results highly depend on the growth characteristics of the individual strain under investigation especially as far as acid production from carbohydrates is concerned. Only species and strains which predominantly form soft, nonfilamentous growth, so that homogeneous cell suspensions can easily be prepared, may give satisfactory results (Funke et al., 1997b). Furthermore, it has been shown (Hall et al., 2003d) that the patterns of physiological characters produced by different test systems may differ considerably for a given actinomycete strain. In a recent comparative study of four commercial systems (RapID ANA II, Rapid ID 32 A, RapID CN Plus, BD Crystal) for identification of *Actinomyces* species and some closely related bacteria (Santala et al., 2004), a strikingly poor applicability of these systems to the fermentative actinomycetes was found not only with new, but also with "classical" species of this genus. These observations confirm the results of Moll et al. (1996) who obtained similar results when comparing the BBL Crystal ANR ID and the API Rapid ID 32 A systems.

For the above reasons, biotyping has gained no practical importance for differentiating *Actinomyces* species below the species level. A bacteriophage typing system has also not been developed. Thus, only serological, SDS-PAGE, and molecular typing methods appear to be suitable for the application to the fermentative actinomycetes.

For serological identification and typing, both direct and indirect modifications of the fluorescent antibody technique have been applied successfully to the fermentative actinomycetes (Schaal and Pulverer, 1973; Slack et al., 1961, 1971) and can be used on culture material as well as on clinical specimens including pus, dental plaque, and calculus or mucosal secretions (Pine et al., 1985). A simple direct fluorescent antibody (FA) procedure was devised by Slack and Gerencser (1975). However, the use of this procedure is limited because fluorescein isothiocyanate (FITC)-conjugated specific antisera to the *Actinomyces* species and serovars are not commercially available, although such antisera for a few species and serovars used to be obtainable from the Biological Reagents Section of the Centers for Disease Control and Prevention (CDC), Atlanta, GA, USA.

*Modified miniaturized system for testing acid production from carbohydrates by fermentative actinomycetes and related organisms (Schofield and Schaal, 1979b, 1980, 1981): I. Basal medium: Thioglycolate broth without glucose or indicator, supplemented with 0.2% (w/v) yeast extract. II. Preparation of carbohydrate-containing filter paper disks: Soak sterile blank filter paper disks (Oxoid) in 3% (w/v) solutions of the various test carbohydrates (filter-sterilized) and dry by lyophilization. III. Test procedure: Prepare the inoculum from 4–7 day-old cultures on BHIA or CC-medium by removing colony material carefully without adhering agar particles and suspend it in basal medium I in a test tube. For strains firmly adhering to the agar, use the dialysis tubing method described above. Homogenize the suspension using a Vortex mixer or a similar mixing device after addition of a few sterile glass beads to the tube. Add 2–3 drops of the densely turbid suspension thus obtained to each well of a microtiter tray with flat bottoms containing one of the sugar-containing disks. Cover the tray with a plastic tape or a plastic cover (when using a tape, perforate it over each well with a sterile injection needle to allow gaseous exchange), and incubate for 2–3 days under adequate gaseous conditions. After incubation, add 1 drop of a 0.2% (w/v) solution of bromothymol blue to each well. Acid production is indicated by a yellow color of the indicator; when the carbohydrate has not been fermented, the color of the indicator is green. A blue-green or blue color is usually due to contamination by organisms not belonging to the genus *Actinomyces*.

†Assessment of nitrate and nitrite reduction and of urease and arginine dihydrolase activities (Schofield and Schaal, 1980, 1981): *I. Basal medium:* Bacto peptone (Difco), 5.0 g; yeast extract (Difco), 3.0 g; glucose, 0.5 g; KH_2PO_4, 2.0 g; agar, 0.5 g; distilled water to reach a total of 1 liter. Adjust the pH to 6.8 and sterilize the medium by autoclaving at 121°C for 15 min. II. Test procedure: Add the test substances to basal medium I from filter-sterilized solutions to obtain the following final concentrations: sodium nitrate, 0.1%; sodium nitrite, 0.005%; urea, 0.5%; arginine, 0.5%. Pipette the various solutions of the test substances into the wells of microtiter trays in volumes of 0.15 ml. Inoculate with suspensions of the test organisms in basal medium I without agar, seal the wells with plastic tape which is perforated as described above, or use a plastic cover. After incubation for 3–4 days, the formation (= nitrate reduction) or disappearance (= nitrite reduction) of nitrite is assessed by adding one drop of the usual nitrite reagent (solution 1: 8.0 g of sulfanilic acid + 1000 ml of 5N acetic acid; solution 2: 5.0 g of α-naphthylamine + 1000 ml of 5N acetic acid. Both solutions are mixed in equal amounts immediately before use). The development of a brick-red color immediately after addition of the reagent indicates the presence of nitrite. If no color develops in the nitrate reduction test, a negative nitrate reduction test is differentiated from the reduction of both nitrate and nitrite by adding a small amount of finely granular zinc which would reduce nitrate to nitrite if the former is still present in the well. Urease activity and deamination of arginine are assessed by means of the ammonia released into the medium when the test is positive. Presence of ammonia is detected by adding 1–2 drops of Nessler's reagent to the wells whereupon a heavy, dark-yellow to ochre precipitate forms immediately. Slowly developing precipitates must be considered as negative results.

To avoid the elaborate and time-consuming labeling procedure for many antisera, Schaal and Pulverer (1973) described an indirect immunofluorescence test* that provides similarly specific results and is even more sensitive than the direct FA modification. For this method, commercially available, FITC-conjugated goat antisera to rabbit globulins are used. The production of the specific rabbit antisera required for serological tests can be performed according to Schaal and Pulverer (1973) or Schaal and Gatzer† (1985).

Whole-cell or cell-wall agglutination as well as immunoblotting procedures (Putnins and Bowden, 1993) may help to solve taxonomic problems, but are not easily applicable to routine identification or differentiation.

Differentiation of the genus *Actinomyces* from other genera

Actinomyces species resemble a variety of other Gram-stain-positive, filamentous, diphtheroidal, or coccobacillary genera morphologically and/or physiologically. This is especially true for the remaining members of the family *Actinomycetaceae* with the exception of *Mobiluncus*, but also for members of the genera *Propionibacterium*, *Bifidobacterium*, and *Erysipelothrix*. Particularly pronounced is the similarity between *Actinomyces israelii* and *Actinomyces gerencseriae* on the one hand and *Propionibacterium propionicum* on the other hand because these species share many diagnostic characters. However, as shown in Table 3, these *Actinomyces* species can be differentiated reliably from *Propionibacterium propionicum* by the presence of LL-A_2pm in the cell walls of and the production of propionic acid as a major end product of glucose fermentation by the latter organism.

Mobiluncus is the only genus that can easily be differentiated from the other members of the family *Actinomycetaceae* by its unique cellular morphology, motility, and variable to negative Gram reaction (Table 3). The other members of the family are much more difficult to differentiate: Only certain *Actinomyces* species produce filamentous cells and/or colonies, a morphological trait that is characteristic, but not exclusive to the genus *Actinomyces* and may, therefore, aid in their differentiation from members of the genera *Actinobaculum*, *Arcanobacterium*, and *Varibaculum* which only form straight to curved, eventually diphtheroidal cells or coccoid structures, possibly with some signs of branching. Additional differential characters may be obtained from chemotaxonomic and acid end product analyses (Table 3).

Other genera which may be confused with *Actinomyces* species can be separated using the characteristics summarized in Table 3. If uncertainties concerning the taxonomic affiliation of an unknown isolate still exist, 16S rRNA gene sequence analyses or other molecular techniques usually help to clarify the situation.

Taxonomic comments

The genus *Actinomyces* was created in 1877, when Harz described the causative agent of bovine actinomycosis which he named *Actinomyces bovis*. Breed and Conn (1919) recommended that *Actinomyces* be considered a *genus conservandum* with *Actinomyces bovis* as the type species. This recommendation was accepted by the Winslow Committee in 1920 (Winslow et al., 1920), thereby confirming that *Actinomyce* Meyen 1827, a name proposed for a fungus (*Tremella meteorica*), was not valid.

Originally, the description of the genus was solely based upon the morphology of the filamentous elements produced by *Actinomyces bovis* in the granules of bovine infections. The discovery of similar, but not identical granules in human infections and the successful cultivation of both *Actinomyces bovis* and *Actinomyces israelii* which included *Actinomyces gerencseriae* at that time added little to this description. Many years later, cultural, physiological, and chemical properties slowly began to influence the definition of the taxon. Pine and Georg (1969) used cellular and colonial morphology, cell-wall composition, fermentation end products, and certain physiological characteristics to define the family *Actinomycetaceae* and the genus *Actinomyces* in light of more modern approaches to taxonomy. Georg et al. (1969) modified the genus description of *Actinomyces* to include catalase-positive organisms to permit the inclusion of *Actinomyces viscosus*. At the same time, *Actinomyces propionicus* was removed from the genus and reclassified as *Arachnia propionica* (now: *Propionibacterium propionicum*) as it produced propionic acid as a major fermentation end product and contained LL-diaminopimelic acid in its cell walls (Pine and Georg, 1969) (Table 3).

Because of persisting taxonomic and nomenclatural uncertainties as well as lack of suitable differential characters, it was essentially impossible for decades to separate *Actinomyces bovis* reliably from *Actinomyces israelii* so that both names were used interchangeably until the reports of Erikson (1940), Thompson (1950), and Pine et al. (1960) finally proved that the causative agents of human and bovine actinomycosis were two taxonomically distinct species.

At the same time, improved taxonomic techniques allowed the delineation of a first group of additional *Actinomyces* species: Thompson and Lovestedt (1951) proposed the name *Actinomyces naeslundii* for a filamentous bacterium that had first been isolated from the human oral cavity by Carl Naeslund in (1925). *Actinomyces viscosus*, which had primarily been described under the genus designation *Odontomyces* (Howell et al., 1965), was

---

*Indirect immunofluorescence procedure for identifying and typing *Actinomyces* species (Schaal and Gatzer, 1985; Schaal and Pulverer, 1973): I. Preparation of smears: a) Clinical material: Make two smears on a clean glass slide containing two marked circles. Fix air-dried smears by flooding with methanol for 1 min. Pour off the alcohol and allow the slide to air-dry. b) Cultures: Make smears of a suspension of the organism obtained by centrifugation of a broth culture or from an agar culture on glass slides, air dry, and gently fix by heating in a Bunsen flame. II. Staining procedure: 1. Place 1 drop of specific rabbit antiserum (possibly absorbed before use) on each smear and incubate the slide in a moist chamber for 30 min at ambient temperature. 2. Pour off excess antiserum and wash the slide in two changes of pH 7.2 buffer (FTA, hemagglutination buffer, BD) for 5 min each. 3. Briefly air-dry the slide. 4. Place 1 drop of FITC-conjugated goat antiserum to rabbit immunoglobulins on the same smear and incubate again in a moist chamber for about 30 min at ambient temperature. 5. Pour off excess conjugate and wash the slide in two changes of pH 7.2 buffer. 6. Counterstain the smear in 0.5% Evans blue for 5 min. 7. Remove excess Evans blue by dipping the slide briefly into distilled water and wash it in two changes of pH 9.0 buffer for 1 min each. 8. Allow the smear to air dry. 9. Place 1 drop of buffered glycerol mounting fluid (9 parts c.p. glycerol, 1 part pH 9.0 buffer) on each smear and cover with a coverslip. 10. For examination with a microscope equipped for FA work, use a 50× water-immersion or an analogous oil-immersion objective.

†Immunization scheme for producing antisera to whole-cell antigens of fermentative actinomycetes (Schaal and Gatzer, 1985; Schaal and Pulverer, 1973): I. Preparation of antigens: Biomass of the reference strains is produced using the dialysis tubing membrane technique (see footnote) on BHIA. The cell suspension is inactivated by heating at 60°C for 20 min in a waterbath, homogenized in a Potter tissue homogenizer, and adjusted to a concentration of 20 mg wet weight per ml. II. Immunization scheme: Ordinary laboratory rabbits can be used, but cross-bred animals may give better immune responses. The immunization schedule with the above suspension is as follows: 1st week: day 1, 1.5 ml i. m.; day 3, 0.5 ml i. v.; day 4, 1.0 ml i. v.; day 5, 1.5 ml i. v.; day 7, 1.5 ml i. m. 2nd week: day 10, 1.5 ml i. v.; day 13, 1.5 ml i. v. 4th week: day 22, test for antibody production. If the antibody titers are below 1:1000, make 2–4 booster i. v. injections at half-weekly intervals. Antiserum is obtained by cardiac puncture in ether anesthesia and lyophilized in 1-ml aliquots until use.

included in the genus *Actinomyces* after its definition changed to accommodate both catalase-positive and catalase-negative species (Georg et al., 1969).

Actinomyces naeslundii and *Actinomyces viscosus* long appeared to be closely related in terms of traditional physiological characters and antigenic structure (Fillery et al., 1978; Holmberg and Hallander, 1973; Schaal and Gatzer, 1985; Schofield and Schaal, 1981). It was even suggested (Gerencser, 1979) that both taxa were varieties of a single species. However, detailed numerical phenetic analyses (Schaal and Schofield, 1981a, 1981b; Schofield and Schaal, 1981) revealed that strains labeled *Actinomyces naeslundii* and *Actinomyces viscosus* formed a set of comparatively stable subclusters, two of which appeared to represent typical *Actinomyces naeslundii* and *Actinomyces viscosus* isolates, respectively. Similarly, in a recent study using a new physiological differentiation system (Taxa Profile, Merlin, Germany), four distinct numerical phenetic clusters could be delineated within the *Actinomyces naeslundii*/*Actinomyces viscosus* complex (N.A. Dahlen, MD thesis, Bonn 2004) showing the heterogeneity of this group of actinomycetes. This heterogeneity had also been suggested by results of DNA–DNA hybridization studies (Coykendall and Munzenmaier, 1979; Johnson et al., 1990) and was definitely confirmed by 16S rRNA gene sequencing (Henssge et al., 2009). The latter study led to the description of *Actinomyces naeslundii sensu stricto* for the former *Actinomyces naeslundii* serovar I or *Actinomyces naeslundii* genospecies 1 according to Johnson et al. (1990), *Actinomyces oris* for the former *Actinomyces naeslundii* serovars II, III, and NV and the former *Actinomyces viscosus* serovar II, which correspond to *Actinomyces naeslundii* genospecies 2 of Johnson et al. (1990), and of *Actinomyces johnsonii* for the former *Actinomyces naeslundii* serovar WVA 963. This revision of the species concept of the *Actinomyces naeslundii*/*Actinomyces viscosus* complex leaves the name *Actinomyces viscosus sensu stricto* for the former serovar I of *Actinomyces viscosus*, which represents the hamster isolates of *Actinomyces viscosus*. *Actinomyces odontolyticus* had primarily been isolated from advanced human carious lesions and was described as a separate *Actinomyces* species by Batty (1958).

After further improvement of the chemotaxonomic and physiological methods and especially after the introduction of DNA–DNA pairing and 16S rRNA gene sequencing technologies into the field of actinomycete taxonomy, numerous additional taxa were added to the list of *Actinomyces* species. Dent and Williams (1984b, 1984c, 1984a, 1986) described three groups of Gram-stain-positive bacteria isolated from the dental plaque of dairy cattle which resembled to some extent *Actinomyces naeslundii* and *Actinomyces viscosus* phenotypically. However, they could be differentiated from these species on the basis of cell wall and DNA base composition, DNA–DNA homology data, polypeptide molecular mass distribution, and a few physiological reactions. These isolates were designated *Actinomyces denticolens*, *Actinomyces howellii*, and *Actinomyces slackii*, respectively, and are all members of the phylogenetic core cluster 1. In contrast, actinomycetes that were isolated from canine infections and named *Actinomyces hordeovulneris* (Buchanan et al., 1984) appear to represent a separate phylogenetic line of descent, possibly together with the species *Actinomyces nasicola*, which was created for a strain recovered from purulent discharge in the nose of a 81-year-old male patient (Hall et al., 2003d).

Actinomyces meyeri, first described by Kurt Meyer (1911), was included in the genus "*Actinobacterium*" by Prévot (1938). However, the genus designation "*Actinobacterium*" lost its standing in nomenclature after the type species of this genus, "*Actinobacterium*" *israelii*, had been transferred to the genus *Actinomyces* by Breed and Conn (1919), so that "*Actinobacterium*" *meyeri* remained "a species in search of a genus" for many years. In 1984, Cato et al. reclassified the organism as *Actinomyces meyeri* and this reclassification is underpinned by 16S rRNA gene sequence data which place the species in the phylogenetic core cluster 2.

The dramatically increasing application of 16S rRNA gene sequencing to the Gram-stain-positive, rod-shaped bacteria in recent years has led to a host of new and reclassified *Actinomyces* species. As far as the classical human species *Actinomyces israelii* is concerned, Stackebrandt and Charfreitag (1990) as well as Johnson et al. (1990) found that strains formerly known as *Actinomyces israelii* serovar II showed a surprisingly low level of DNA relatedness to *Actinomyces israelii* serovar I which prompted the latter authors to propose the new species *Actinomyces gerencseriae* for the serovar II strains. In the same study, Johnson et al. (1990) created the species *Actinomyces georgiae* whose members were recovered from gingival crevices of humans with and without periodontitis. However, while *Actinomyces gerencseriae* belongs to the phylogenetic core cluster 1, *Actinomyces georgiae* is found in core cluster 2.

Another group of organisms which had primarily been termed CDC group 1 coryneform bacteria and CDC group 1-like coryneform bacteria were assigned to the genus *Actinomyces* as *Actinomyces neuii* subsp. *neuii* and *Actinomyces neuii* subsp. *anitratus*, respectively (Funke et al., 1994) although current phylogenetic data indicate that these bacteria represent a separate line of descent only loosely affiliated with *Actinomyces* core cluster 2. *Actinomyces radingae* and *Actinomyces turicensis*, which were both chiefly isolated from human mixed infections, are members of core cluster 2.

Actinomyces-like bacteria that had predominantly been recovered from human respiratory tract secretions were described as *Actinomyces graevenitzii* (Pascual Ramos et al., 1997a). However, several trees derived from 16S rRNA gene sequences show unequivocally that *Actinomyces graevenitzii* occupies an isolated phylogenetic position within the *Actinomycetaceae*. Similarly, *Actinomyces europaeus* (which was proposed as a new *Actinomyces* species by Funke et al. (1997a) is only remotely related to the classical *Actinomyces* species in terms of 16S rRNA gene sequence similarity, but exhibits some relationship to *Actinomyces coleocanis*, a species found in the vagina of dogs (Hoyles et al., 2002a).

In contrast, *Actinomyces urogenitalis* which had been isolated from the human urogenital tract (Nikolaitchouk et al., 2000) is a true member of phylogenetic core cluster 1 while *Actinomyces funkei* (which was proposed by Lawson et al. (2001b) for three human strains of different sources including blood cultures) is found in core cluster 2. The most recent novel species of the genus *Actinomyces* from human sources apparently belong to different phylogenetic lines of descent. *Actinomyces cardiffensis* which was described by Hall et al. (2002) had been isolated from various clinical specimens including IUCDs and is also a member of core cluster 2. In contrast, strains recovered from infected human dental root canals and designated *Actinomyces radicidentis* (Collins et al., 2000) are associated with core cluster 1 (Schaal et al., 2006) or possibly more closely with *Actinomyces graevenitzii* (Figure 19).

Another new *Actinomyces* species of human origin, *Actinomyces oricola* Hall et al. 2003c, was isolated from a dental abscess and shows some relatedness to the subgroup in core cluster 1 which contains *Actinomyces gerencseriae* and *Actinomyces israelii*. An additional new species from a human clinical specimen and designated *Actinomyces hongkongensis* (Woo et al., 2003) shows some 16S

rRNA gene sequence relatedness to the new animal species *Actinomyces marimammalium* (Hoyles et al., 2001c), which was isolated from seals and a porpoise. These two species form a subcluster in the phylogenetic tree related to core cluster 2 and may represent a separate line of descent. The definition of *Actinomyces houstonensis* which was proposed by Clarridge and Zhang in (2002) for three human isolates from serious subcutaneous abscesses, was primarily based upon 16S rRNA gene sequence data, while its phenotypic characterization remained fragmentary. In addition, the species has not yet been validated so that it will be listed under "*Species incertae sedis*". Details on a species named *Actinomyces lingnae* mentioned in the paper of Clarridge and Zhang (2002) could be found neither in the international literature nor in the catalogs of relevant international culture collections.

Additional novel *Actinomyces* species have been cultured from various animal sources: The designation *Actinomyces hyovaginalis* was proposed for a group of *Actinomyces*-like isolates that were derived from purulent discharge and aborted fetuses of pigs (Collins et al., 1993). These organisms are members of phylogenetic core cluster 2. Fermentative Gram-stain-positive bacteria isolated from pigs and designated "*Actinomyces suis*" have caused taxonomic and nomenclatural problems over many years. This species epithet was first used by Gasperini (1892), but had not been validly published and was therefore declared a *nomen dubium* (Slack, 1974). Grässer (1957) cultured bacteria from mastitis of swine and named them also "*Actinomyces suis*". In this case, the name was validly published, but the description was inadequate and cultures were not available. More recently, Franke (1973) once more described actinomycetes isolated from the udders of swine as "*Actinomyces suis*". The description of Franke's isolates appears to differ from that of Grässer's strains, but is strikingly similar to that of *Actinomyces hyovaginalis* (Collins et al., 1993) at least as far as physiological characteristics are concerned. Another single bacterial isolate from pig mastitis was found to represent a further new *Actinomyces* species belonging to core cluster 2 and was named *Actinomyces suimastitidis.*

Several additional new animal *Actinomyces* species originated from canine and/or feline clinical lesions. *Actinomyces bowdenii* Pascual et al., 1999 was recovered from various pathological processes in dogs and cats, predominantly in mixed culture with other microbes, and is a member of core cluster 1. *Actinomyces canis* Hoyles et al., 2000 was cultured from either vaginal secretions or pus of dogs and belongs to core cluster 2. A third canine species, *Actinomyces catuli* Hoyles et al., 2001c, was isolated from a polymicrobial infection of the lungs and the pleural space and is a border-line member of core cluster 1, possibly with some phylogenetic relationship to *Actinomyces graevenitzii* and *Actinomyces radicidentis.* The phylogenetic affiliation of *Actinomyces coleocanis* (Hoyles et al., 2002b) from the vagina of a cocker spaniel dog has already been mentioned.

The most recent animal *Actinomyces* species, *Actinomyces vaccimaxillae* (Hall et al., 2003d) from a jaw lesion of an adult cow and *Actinomyces ruminicola* (An et al., 2006) from cattle rumen, are members of core cluster 2 and core cluster 1, respectively. The species "*Actinomyces humiferus*" Gledhill and Casida 1969 differs considerably from typical members of the genus *Actinomyces* in that it grows at 30°C, has a high G+C content of its DNA (73 mol%), is sensitive to lysozyme, and occurs in high numbers in organically rich soils (Gledhill and Casida, 1969). Also, it was found to be unrelated phylogenetically to true *Actinomyces* species and was thus reclassified as *Cellulomonas humilata* (Collins and Pascual, 2000).

Similarly, "*Actinomyces eriksonii*" Georg, Robertstad, Brinkman, and Hicklin 1965, when primarily characterized, appeared to resemble members of the genus *Actinomyces* in terms of cellular and colonial morphology, oxygen requirements, cell-wall composition, and pathogenicity. However, additional and more detailed analyses showed that its fermentation end products as well as its cell-wall structure were those of bifidobacteria (Moore, 1970; Slack and Gerencser, 1975). Mitsuoka et al. (1974) claimed that "*Actinomyces eriksonii*" was identical with *Bifidobacterium adolescentis* Reuter (1963). As *Bifidobacterium adolescentis* and *Bifidobacterium dentium* are closely related and as it is even impossible to differentiate biovars *b* and *d* of *Bifidobacterium adolescentis* phenotypically from *Bifidobacterium dentium* (Scardovi, 1986), it is not very surprising that DNA of the type strain of "*Actinomyces eriksonii*" (ATCC 15423) is completely homologous with that of a *Bifidobacterium dentium* strain (Scardovi, 1986).

Further reclassifications involved "*Actinomyces bernardiae*" Funke et al. 1995 and "*Actinomyces pyogenes*" Reddy et al. 1982, which were both transferred to the genus *Arcanobacterium* as *Arcanobacterium bernardiae* and *Arcanobacterium pyogenes*, respectively (Pascual Ramos et al., 1997b). "*Actinomyces suis*" Ludwig et al. 1992 which had primarily been described as *Eubacterium suis* Wegienek and Reddy 1982 and differed from the swine isolates mentioned as "*Actinomyces suis*" above, was reclassified as *Actinobaculum suis* Lawson et al. 1997.

The heterogeneity of the genus *Actinomyces* as currently recognized is suggested by 16S rRNA gene sequence data that separate the genus into two major phylogenetic clusters (core clusters 1 and 2) and at least five subclusters possibly representing additional separate lines of descent. A subdivision of the genus is also suggested by numerical phenetic results (Schofield and Schaal, 1981) and chemotaxonomic findings (Schaal et al., 2006). In this respect, the prediction Schaal (1986b) made in the previous edition of *Bergey's Manual* concerning the future taxonomic development of the genus is now known to be true without reservation. However, as many *Actinomyces* species have as yet been characterized incompletely, especially as far as chemotaxonomy is concerned, it still appears to be premature to formally subdivide the genus *Actinomyces* into three or even more new genera. Nevertheless, as the type species of the genus, *Actinomyces bovis*, is found in core cluster 1, species such as *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces johnsonii*, *Actinomyces naeslundii*, *Actinomyces oris*, and the remaining species of core cluster 1 may retain the genus designation *Actinomyces* in the future.

Identification and descriptive characteristics of *Actinomyces* species

The phenotypic characteristics useful for identification of the recognized *Actinomyces* species are given in Table 4 and Table 5. Table 6 and Table 8 summarize the morphological properties of human and animal *Actinomyces* species. Additional descriptive details of both groups of *Actinomyces* species are listed in Table 7 and Table 9.

β-Hemolysis	–	(d)	–	–	–	–	–	–	–	–	nr	–	–	d	–	nr	(+)	(+)	nr	–	–	–	–	nr

[a]Symbols: +, positive/present; –, negative/absent; +/–, predominantly positive/present; –/+, predominantly negative/absent; (+), weakly or irregularly positive/present; d, strain differences; (d), some strains weakly positive; –[+], acid production by *Actinomyces massiliensis* usually detected after 24 h, with some strains showing a positive result after 48 h; nr, not reported.

[b]Data compiled from Schaal (1986b), Johnson et al. (1990), Vandamme et al. (1998), Hall et al. (2005), Schaal et al. (2006), Henssge et al. (2009), and Renvoise et al. (2009).

[c]The negative acid production tests from carbohydrates may be due to the use of an inadequate commercial test system in the original description of the species.

[d]Animal species included for comparison.

[a]Symbols: +, positive/present; –, negative/absent; d, positive or negative, possibly depending on the system used; +/–, usually positive; –/+, usually negative; (), weak reaction; –[+], acid production by *Actinomyces massiliensis* usually detected after 24 h, with some strains showing positive reactions after 48 h.

[b]Data compiled from: Schofield and Schaal (1981); Cato et al. (1984); Schaal (1986b); Johnson et al. (1990); Funke et al. (1994, 1997a); Wüst et al. (1995a); Pascual Ramos et al. (1997a); Collins et al. (2000); Nikolaitchouk et al. (2000); Lawson et al. (2001b); Sarkonen et al. (2001); Hall et al. (2002, 2003c, 2003d, 2005); Woo et al. (2003); Henssge et al. (2009); Renvoise et al. (2009).

[c]The negative acid production tests from carbohydrates may be due to the use of an inadequate commercial test system in the original description of the species.

[d]Animal species included for comparison.

(1993), Pascual et al. (1999), Hoyles et al. (2000, 2001a, 2001b, 2001c, 2002a, 2002b); Hall et al. (2003a), and An et al. (2006).

List of species of the genus *Actinomyces*

1. **Actinomyces bovis** Harz 1877, 133[AL] (*Discomyces bovis* Harz 1877) Rivolta 1878; *Sarcomyces bovis* (Harz 1877) Rivolta 1879; *Oospora bovis* (Harz 1877) Sauvageau and Radais 1892; *Actinocladothrix bovis* (Harz 1877) Gasperini 1892; *Nocardia bovis* (Harz 1877) Blanchard 1896; *Streptothrix bovis* (Harz 1877) Chester 1901; *Cladothrix bovis* (Harz 1877) Macé 1901; *Sphaerotilus bovis* (Harz 1877) Engler 1907; *Proactinomyces bovis* (Harz 1877) Henrici 1939

bo′vis. L. masc. and fem. n. *bos* ox, cow; L. gen. n. *bovis* of the ox/cow.

Cells of *Actinomyces bovis* are usually short and diphtheroidal (Figure 24), but short branching rods (Figure 21) may occur while long multibranched filaments are rarely seen. The two serovars recognized within the species are most easily and reliably identified by direct or indirect fluorescent antibody techniques. In addition, the microcolonies of serovar I strains are usually smooth with an entire to irregular edge, slightly raised to convex, white to colorless and soft and show only occasionally short radiating filaments at the edge (Figure 35), while serovar II microcolonies tend to be filamentous (Figure 39) and may even resemble *Actinomyces israelii* microcolonies (Figure 30). Mature *Actinomyces bovis* colonies are 0.5–1.0 mm in diameter, circular, with a smooth or finely granular surface, convex, entire-edged, and usually soft (Figure 49). Strains producing filamentous microcolonies also form rough macrocolonies resembling the molar-tooth or bread-crumb colony type of *Actinomyces israelii* (Figure 51). Catalase-negative. Further morphological details, ultrastructure, cell-wall composition, nutrition and growth conditions, metabolism, and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. The natural habitat is not definitely known especially because in studies on the plaque flora of dairy cattle, *Actinomyces bovis* could not be identified (Dent and Williams, 1984b, 1984c, 1986). However, given the apparently endogenous origin of bovine infections, the natural habitat is assumed to be the oral cavity and/or the intestinal tract of cattle and possibly other animals. *Actinomyces bovis* is the causative agent of actinomycosis in cattle (bovine actinomycosis, lumpy jaw). The etiology of similar infections in other animals, including a llama, has not been clarified with certainty although it has been claimed that at least some of these diseases might also be due to *Actinomyces bovis*. In contrast, this species has never been proved to cause actinomycosis in man, nor has it been isolated from human mucosal surfaces or other human sources. Experimental infections have been produced in hamsters, mice and a few other animal species after intraperitoneal, intravenous or subcutaneous injections of viable cell suspensions.

Source: a typical case of lumpy jaw in a cow.

DNA G+C content (mol%): 57–63 (T_m).

Type strain: ATCC 13683, CIP 103258, NCTC 11535, CCUG 31996, DSM 43014 (serovar I).

Reference strain for serovar II: WVU 292.

Sequence accession no. (16S rRNA gene): X81061.

2. **Actinomyces bowdenii** Pascual, Foster, Falsen, Bergström, Greko and Collins 1999, 1876[VP]

bow.de′ni.i. N.L. gen. masc. n. *bowdenii* of Bowden, to honor George H. Bowden, a contemporary British microbiologist, who made many valuable contributions to actinomycete microbiology.

Cells are straight or slightly curved rods, 2–4 µm in length, some of which exhibit branching. Colonies on blood agar are non-hemolytic, grayish-white, circular, and approximately 2 mm in diameter after 24–48 h of aerobic incubation. Growth is not enhanced by increased concentrations of CO_2. Catalase-positive. Additional morphological details, chemotaxonomic markers, nutrition, and growth conditions and metabolic activities are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. The natural habitat is not definitely known.

Source: clinical materials from dogs and a cat. The type strain was from an abscess under the mandible of a dog.

DNA G+C content (mol%): not reported.

Type strain: M1327/96/1. CCUG 37421, CIP 106647, DSM 15435.

Sequence accession no. (16S rRNA gene): AJ234039.

3. **Actinomyces canis** Hoyles, Falsen, Foster, Pascual, Greko and Collins 2000, 1549[VP]

ca′nis. L. masc. and fem. n. *canis* dog, bitch; L. gen. n. *canis* of the dog/bitch.

Cells are straight to slightly curved rods, some of which exhibit branching. Catalase-positive. Additional morphological details, nutrition and growth conditions, and metabolic activities are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. *Actinomyces canis* can be readily distinguished from other *Actinomyces* species by physiological characteristics and SDS-PAGE analysis of whole-cell proteins. The natural habitat is not known.

Source: canine vagina, a fatal pyogranulomatous pleurisy of a foxhound bitch, and a subcutaneous abscess in a female hunting dog, exclusively in mixed culture with other aerobic and anaerobic bacteria. The type strain was isolated from the vagina of a dog with a history of infertility.

DNA G+C content (mol%): not reported.

Type strain: M2289/98/2, CCUG 41706, CIP 106351, DSM 15536.

Sequence accession no. (16S rRNA gene): AJ243891.

4. **Actinomyces cardiffensis** Hall, Collins, Hutson, Falsen and Duerden 2003f, 1[VP] (Effective publication: Hall, Collins, Hutson, Falsen and Duerden 2002, 3429.)

car.dif.fen′sis. N.L. masc. adj. *cardiffensis* of or pertaining to Cardiff, a city in Wales.

Cells are pleomorphic, slender, straight to curved rods; beaded branching filaments occur. On Fastidious Anaerobe Agar with 5% horse blood after 48 h of incubation, colonies are pinpoint, convex, smooth-surfaced, entire-edged, opaque, cream to pinkish, and non-hemolytic.

Catalase-negative. Additional morphological details, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The natural habitat is not known.

Source: human clinical sources, including IUCDs, pleural fluid, brain, jaw, pericolic and ear abscesses, and nasal antrum. The type strain was isolated from an intrauterine contraceptive device, which had been *in situ* for 7 years in a 35-year-old woman.

DNA G+C content (mol%): not reported.

Type strain: R10394, CCUG 44997, CIP 107323, DSM 15803.

Sequence accession no. (16S rRNA gene): AJ421779.

5. **Actinomyces catuli** Hoyles, Falsen, Pascual, Sjödén, Foster, Henderson and Collins 2001b, 681[VP]

ca'tu.li. L. masc. n. *catulus* young dog; L. masc. gen. n. *catuli* of a small dog.

Cells are straight to slightly curved rods. Colonies are tiny, irregular, convex, white, and adherent to medium at colony base. Catalase-negative or weakly catalase-positive. Additional morphological details, nutrition and growth conditions, and metabolism and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. In SDS-PAGE analysis, the *Actinomyces catuli* isolates formed a distinct group which was separate from all *Actinomyces* species described until 2001. The natural habitat is not known.

Source: polymicrobial infection of a dog with pneumonia and exudative pleurisy and from a dog from which no information on the clinical background was available. The type strain was isolated from mediastinal tissue and blood clot of a dog with pneumonia and exudative pleurisy together with *Bacteroides fragilis*, *Fusobacterium nucleatum*, *Peptostreptococcus anaerobius*, and *Ruminococcus (Peptostreptococcus) productus.*

DNA G+C content (mol%): not reported.

Type strain: M1192/98/1, CCUG 41709, CIP 106507, DSM 15415.

Sequence accession no. (16S rRNA gene): AJ276805.

6. **Actinomyces coleocanis** Hoyles, Falsen, Foster and Collins 2002a, 1203[VP]

co.le.o.ca'nis. Gr. masc. n. *koleos* sheath, vagina; L. masc. and fem. n. *canis* dog, bitch; N.L. gen. n. *coleocanis* of the vagina of a bitch.

Cells are straight to slightly curved rods, some of which exhibit branching. Catalase-negative. Additional morphological details, nutrition, and growth conditions, as well as metabolism and metabolic pathways, are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. Upon comparative analysis of SDS-PAGE whole-cell protein profiles, the single strain of *Actinomyces coleocanis* formed a distinct line and did not show a particularly close affinity with any recognized *Actinomyces* species. The natural habitat is not known.

Source: mixed culture with "*Corynebacterium genitalium*" from the vagina of a cocker spaniel dog. The type strain was isolated from the vagina of a dog.

DNA G+C content (mol%): not reported.

Type strain: M343/98/2, CCUG 41708, CIP 106873, DSM 15436.

Sequence accession no. (16S rRNA gene): AJ249326.

7. **Actinomyces dentalis** Hall, Collins, Lawson, Falsen and Duerden 2005, 430[VP]

den.ta'lis. L. masc. n. *dens, dentis* tooth; L. masc. suff. *-alis* suffix denoting pertaining to; N.L. masc. adj. *dentalis* pertaining to teeth.

Cells are rod-shaped or filamentous and beaded. After 48 h of anaerobic incubation on Fastidious Anaerobe Agar with 5% horse blood, colonies are tiny, white and breadcrumb-like and pit the agar. Catalase-negative. Additional morphological details, nutrition and growth conditions, as well as metabolism and metabolic pathways, are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The natural habitat is not known.

Source: pus of a dental abscess from a 72-year-old female patient with facial swelling. The type strain was isolated from a human dental abscess.

DNA G+C content (mol%): 62 (HPLC).

Type strain: R18165, CCUG 48064, CIP 108337, DSM 19115.

Sequence accession no. (16S rRNA gene): AJ697609.

8. **Actinomyces denticolens** Dent and Williams 1984d, 503[VP] (Effective publication: Dent and Williams 1984b, 188.)

den.ti.co'lens. L. masc. n. *dens, dentis* tooth; L. v. *colere* to inhabit, to dwell; L. part. adj. *colens* dwelling; N.L. part. adj. *denticolens* tooth-dwelling.

Cells are rod-shaped and straight or slightly curved (mean, 0.7 µm × 5 µm; Figure 25), but may also be very short. Microcolonies are usually flat and non-filamentous (Figure 38), but may show a few peripheral hyphae radiating from the granular center (Figure 37); very young microcolonies may be completely filamentous (Figure 40). Mature colonies on horse blood agar are slightly pink when grown anaerobically, but white if grown aerobically. They are circular, entire, convex, and smooth (Figure 55). Catalase-negative. Additional morphological details, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways, and drug susceptibility are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. The patterns of polypeptides as analyzed by SDS-PAGE are unique, although with some intraspecies variation, and allow the species to be distinguished from both *Actinomyces naeslundii* and *Actinomyces howellii* with which it shares several physiological and biochemical characters. Immunoblotting showed that *Actinomyces denticolens* was between 39% and 72% similar to *Actinomyces naeslundii* and *Actinomyces viscosus*, while whole-cell agglutination clearly differentiated *Actinomyces denticolens* from *Actinomyces naeslundii sensu stricto.* The normal habitat of *Actinomyces denticolens* is the oral cavity, especially dental plaque, of cattle. Pathogenicity has not been reported.

Source (type strain): supragingival plaque of dairy cattle.

DNA G+C content (mol%): 66–68 (T_m).

Type strain: Sh 8/4303, CIP 103126, ATCC 43322, CCUG 32758, DSM 20671, NCTC 11490.

Sequence accession no. (16S rRNA gene): X80412.

9. **Actinomyces europaeus** Funke, Alvarez, Pascual, Falsen, Åkervall, Sabbe, Schouls, Weiss and Collins 1997a, 690[VP]

eu.ro.pa′e.us. L. masc. adj. *europaeus* European, referring to the fact that six different European laboratories contributed to the description of the species.

Cells are short (0.5–1.5 µm in length) rods that sometimes are arranged in clusters. Colonies are circular and smooth with a translucent grayish appearance. After 48 h of incubation in a 5% CO_2-enriched atmosphere, their diameter is not greater than 0.5 mm. Catalase-negative. Additional morphological details, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7.

The natural habitat of *Actinomyces europaeus* is not definitely known.

Source: human abscesses. The type strain was isolated from femur tissue of a 63-year-old man.

DNA G+C content (mol%): 61–63 (HPLC).

Type strain: ATCC 700353, CCUG 32789A, CIP 105308, LMG 18454.

Sequence accession no. (16S rRNA gene): Y08828.

10. **Actinomyces funkei** Lawson, Nikolaitchouk, Falsen, Westling and Collins 2001b, 855[VP]

fun′ke.i. N.L. gen. masc. n. *funkei* of Funke, to honor Guido Funke, a contemporary German microbiologist, for his contributions to the clinical microbiology of *Actinobacteria*.

Cells are slender, straight to slightly curved rods, some of which exhibit branching. When grown on Columbia horse blood agar for 24 h in air plus 5% CO_2, colonies are small (<1 mm in diameter), gray, and non-hemolytic. Older cultures display fried-egg-type colony morphology. Catalase-negative. Additional morphological details as well as nutrition and growth conditions are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. In SDS-PAGE analysis, the *Actinomyces funkei* isolates were highly related to each other and were distinct from recognized *Actinomyces* species. The natural habitat is not definitely known.

Source: human clinical specimens (blood cultures, sternum and abdominal incision). The type strain was isolated from three blood cultures from a 40-year-old female intravenous drug user who had a history of *Staphylococcus aureus* endocarditis of the tricuspid valve.

DNA G+C content (mol%): not reported.

Type strain: CCUG 42773, CIP 106713, DSM 15537.

Sequence accession no. (16S rRNA gene): AJ404889.

11. **Actinomyces georgiae** Johnson, Moore, Kaneko and Moore 1990, 276[VP]

ge.or.gi′a.e. N.L. gen. fem. n. *georgiae* of Georg, to honor Lucile K. Georg, a pioneer in *Actinomyces* taxonomy.

Cells grown in peptone-yeast extract-glucose broth for 24 h are 0.9–1.0 µm wide and 3.3–6.1 µm long. Without addition of a fermentable carbohydrate, cells are shorter and may even be coccoid. The rods occur in pairs and short chains and may have swellings; branching is seldom seen. Best growth is obtained when the cultures are incubated anaerobically. Colonies are circular, entire, pulvinate, translucent to opaque, white (27% are tan or beige), shiny, and smooth. Their diameter ranges from 0.5 to 2.0 mm. Addition of 0.02% Tween 80 to broth media enhances growth and fermentation of 62% of the strains. Catalase-negative. Additional morphological details, nutrition and growth conditions, metabolism and metabolic pathways are as given for the genus or as summarized in Table 6. Physiological and other descriptive or differential characteristics are listed in Table 4 and Table 7. *Actinomyces georgiae* cells do not react with FITC-labeled antisera to *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces johnsonii*, *Actinomyces meyeri*, *Actinomyces naeslundii*, *Actinomyces odontolyticus* serovars I and II, and *Actinomyces oris*. *Actinomyces georgiae* has been isolated from human gingival crevices. It accounts for about 1.4% of the human healthy periodontal flora. The species has usually been considered nonpathogenic. However, a recent report suggests that it might be a rare causative agent of endocarditis in man.

Source (type strain): gingival crevice of a child.

DNA G+C content (mol%): 65–69 (T_m).

Type strain: ATCC 49285, CCUG 32935, CIP 104749, DSM 6843, VPI D145A-7.

Sequence accession no. (16S rRNA gene): X80413.

12. **Actinomyces gerencseriae** Johnson, Moore, Kaneko and Moore 1990, 278[VP]

ge.renc.se.ri′ae. N.L. gen. fem. n. *gerencseriae* of Gerencser, to honor the American microbiologist Mary Ann Gerencser, an authority on *Actinomyces* species.

Cellular and colonial morphology are similar to those of *Actinomyces israelii*: microcolonies may be highly filamentous and spider-like (Figure 28 and Figure 29), but may also be less filamentous with a few projecting short filaments and a fragmented center (Figure 31). Mature colonies may be highly filamentous even showing short aerial hyphae (Figure 43), but smooth and soft colonies are quite common (Figure 44). Catalase-negative. Additional morphological details, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The type strain and 12% of the other isolates tested were obligately anaerobic. The pH in peptone-yeast extract-glucose-Tween 80 medium incubated 3–5 d is 4.3–5.3. Addition of Tween 80 to broth medium increases the growth of 25% of the cultures and does not affect the growth of 75%. The species is distinct from *Actinomyces israelii sensu stricto* as determined by polyacrylamide gel electrophoresis banding patterns, serological reactions, and the inability to ferment L-arabinose.

The normal habitat of *Actinomyces gerencseriae* is the oral cavity of man including tonsillar crypts and dental plaque. The species was found to account for 1.2% of the human healthy periodontal flora and occurred in 14% of the samples examined. The respective figures in patients with

gingivitis and periodontitis were 1.5% and 17%. It apparently also occurs in lower numbers in the human intestinal and female genital tracts. *Actinomyces gerencseriae* is one of the typical causative agents of human cervicofacial and other actinomycoses. It has also been isolated from retroperitoneal abscesses, hand abscesses, and various other clinical conditions. Experimental animal infections are similar to or identical with those produced by *Actinomyces israelii*.

Source (type strain): human parotid abscess.

DNA G+C content (mol%): 70–71 (T_m).

Type strain: ATCC 23860, CCUG 32936, CCUG 34703, CDC W 838, CIP 105418, DSM 6844, JCM 12963, VPI 12594.

Sequence accession no. (16S rRNA gene): X80414.

13. **Actinomyces graevenitzii** Pascual Ramos, Falsen, Alvarez, Åkervall, Sjöden and Collins 1997a, 887[VP]

gra.e.ve.nit′zi.i. N.L. gen. masc. n. *graevenitzii* of Graevenitz, to honor Alexander von Graevenitz, a contemporary clinical microbiologist, for his many contributions to clinical microbiology.

Cells are straight or slightly curved rods that exhibit some branching and have swollen ends. Colonies on blood agar, incubated in the presence of 5% CO_2, are non-pigmented, opaque, and approximately 0.2 mm in diameter after 24 h of incubation; they adhere to agar surfaces. Catalase-negative. Additional morphological details, chemotaxonomic markers, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The natural habitat of *Actinomyces graevenitzii* appears to be the oral cavity of man, especially of children.

Source: human clinical specimens, in particular respiratory tract secretions and an osteitis of the jaw. The type strain was isolated from a bronchus brush of a 57-year-old woman.

DNA G+C content (mol%): not reported.

Type strain: CCUG 27294, CIP 105737, DSM 15540.

Sequence accession no. (16S rRNA gene): AJ540309.

14. **Actinomyces hominis** Funke, Englert, Frodl, Bernard, and Stenger 2010, 1679[VP]

ho′mi.nis. L. masc. n. *homo, hominis* man; L. gen. n. *hominis* of man, indicating that the type strain was isolated from a human.

Cells are Gram-stain-positive, diphtheroidal rods that do not stain partially acid-fast; filamentous forms are not observed. Mycolic acids are absent. The main straight-chain saturated cellular fatty acids are palmitic (32%) and stearic acids (15%); small amounts of decanoic, dodecanoic, and tetradecanoic acids are also detected. Oleic acid (39%) is the predominant unsaturated fatty acid. The type strain grows equally well under aerobic and anaerobic conditions. After 72 h of incubation on sheep blood agar at 35°C in a CO_2-enriched atmosphere, colonies are white-grayish, convex, non-lipophilic (i.e., do not take up Sudan Black or Oil Red-O), and 1 mm in diameter. Catalase-positive. When using the API Coryne, API ZYM, and API 50 CHB systems, acid is produced from D-adonitol, L-arabinose, D- and L-arabitol, erythritol, D-fructose, D-galactose, potassium gluconate, potassium 5-ketogluconate, methyl α-D-glucopyranoside, D-glucose, glycerol, glycogen, inositol, maltose, D-mannose, melezitose, raffinose, D-ribose, sucrose, starch, and turanose, but not from amygdalin, D-arabinose, arbutin, cellobiose, dulcitol, D- and L-fucose, gentiobiose, potassium 2-ketogluconate, *N*-acetylglucosamine, inulin, lactose, D-mannitol, methyl α-D-mannopyranoside, melibiose, L-rhamnose, salicin, D-sorbitol, L-sorbose, D- and L-xylose, or methyl β-D-xylopyranoside. Nitrate is reduced to nitrite. Pyrazinamidase, acid and alkaline phosphatase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, α- and β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase are produced, but not urease, gelatinase, pyrrolidonyl arylamidase, β-glucuronidase, esterase (C4), lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, β-glucosidase, or α-fucosidase. CAMP reaction with *Staphylococcus aureus* ATCC 25923 is positive. Using the microdilution method for coryneform bacteria, the type strain exhibited susceptibility to cefotaxime, doxycycline, erythromycin, linezolid, meropenem, penicillin G, and vancomycin. In the neighbor-joining phylogenetic tree based on 16S rRNA gene sequences, *Actinomyces hominis* clustered near *Actinomyces europaeus* and *Actinomyces coleocanis*. The natural habitat is not known.

Source (type strain): a wound swab taken from an 89-year-old human female patient.

DNA G+C content (mol%): not reported.

Type strain: 1094, 7894GR, CCUG 57540, DSM 22168.

Sequence accession no. (16S rRNA gene): FJ617539.

15. **Actinomyces hongkongensis** Woo, Fung, Lau, Teng, Wong, Wong, Hon, Tang and Yuen 2004, 307[VP] (Effective publication: Woo, Fung, Lau, Teng, Wong, Wong, Hon, Tang and Yuen 2003, 521.)

hong.kong.en′sis. N.L. masc. adj. *hongkongensis* of or pertaining to Hong Kong, where the type strain was isolated.

Cells are straight rods. On sheep blood agar after 24 h of anaerobic incubation, colonies are pinpoint and non-hemolytic. Catalase-negative. Additional morphological details as well as nutrition and growth conditions are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The natural habitat is not known.

Source (type strain): pus from the Fallopian tubes of a 36-year-old Chinese woman with IUCD-related pelvic actinomycosis.

DNA G+C content (mol%): not reported.

Type strain: HKU 8, CCUG 48484, DSM 15629, CIP 107949, LMG 21939.

Sequence accession no. (16S rRNA gene): AF433168.

16. **Actinomyces hordeovulneris** Buchanan, Scott, Gerencser, Beaman, Jang and Biberstein 1984, 442[VP]

hor.de.o.vul′ne.ris. L. neut. n. *hordeum* barley; N.L. n. *Hordeum* genus of grass; L. neut. n. *vulnus, vulneris* wound, injury; N.L. gen. n. *hordeovulneris* of (isolated from) injuries produced by awns of *Hordeum*.

Cells are pleomorphic rods and filaments that are 0.5–1.0 μm in diameter and usually exhibit a noticeable degree of

branching on blood agar. In broth supplemented with 15% fetal bovine serum, the filaments are long and extensively branched and have swollen ends, where sphaeroplast-like bodies occasionally develop. Fragmentation into diphtheroidal cells is incomplete in broth cultures.

Microcolonies on BHIA supplemented with 10–20% fetal bovine serum after 24 h of incubation are regularly filamentous and similar to those of *Actinomyces israelii*. Mature colonies on bovine blood agar are white, agar-adherent, and molar-toothed, with a tendency to shift to a white, conical, domed, buttery, less adherent type upon laboratory passage. Diameters are 0.5–1.0 mm after 48 h and 2 mm after 3 d. Growth is weak in trypticase soy broth both aerobically and anaerobically unless the medium is supplemented with serum. Catalase activity was found to be weak to moderate in all of the strains tested. Additional morphological details, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus or as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9.

Preliminary serological data obtained with FITC-conjugated antisera to various *Actinomyces* and *Rothia* species showed some degree of cross-reactivity between conjugates of the type strains of *Actinomyces israelii* (ATCC 12102) and *Actinomyces viscosus* (ATCC 15987) and *Actinomyces hordeovulneris* cells. Significant cross-reactions were not observed with antisera to *Actinomyces oris*, *Actinomyces gerencseriae*, *Actinomyces bovis* serovars I and II, *Actinomyces naeslundii*, *Actinomyces odontolyticus* serovars I and II, "*Actinomyces suis*", *Arcanobacterium pyogenes*, or to the serovars of *Rothia dentocariosa*. The normal habitat of *Actinomyces hordeovulneris* remains to be definitely clarified. However, the organism has been isolated from the gingival margin of healthy cats so that it might be assumed that it belongs to the indigenous microflora of the oral cavity of cats and possibly dogs. *Actinomyces hordeovulneris* is well established as a pathogen of dogs in which it may produce pleuritis, pericarditis, peritonitis, visceral abscesses, septic arthritis, and recurrent localized suppurations in which sulfur granule-like particles may be found. These infections often occurred secondary to injuries caused by tissue-migrating awns of several members of the grass genus *Hordeum* (commonly called foxtails) which are common in the Western United States, especially California. Some of the infected animals died despite ampicillin treatment although this drug was effective *in vitro*. The unfavorable responses to ampicillin were attributed to a marked tendency of *Actinomyces hordeovulneris* to produce L-phase variants spontaneously with coincident uptake of calcium and may additionally be due to the formation of sulfur granules.

Source (type strain): An infection secondary to tissue-wandering foxtail awns.

DNA G+C content (mol%): 67–68 (Bd).

Type strain: ATCC 35275, CCUG 32937, CIP 103149, DSM 20732, UCD 81-332-9.

Sequence accession no. (16S rRNA gene): X82448.

17. **Actinomyces howellii** Dent and Williams 1984c, 319[VP]

how.el′li.i. N.L. gen. masc. n. *howellii* of Howell, to honor the American microbiologist Arden Howell Jr, who studied oral actinomycetes from animals, particularly *Odontomyces* (*Actinomyces*) *viscosus*.

Cells are rod-shaped (0.8 µm wide × 1.5–5.0 µm long) and may show characteristic Y, V, and T forms. Short filaments may be present. Mature colonies when grown anaerobically on horse blood agar for 3–5 d are white, smooth, shiny, translucent, convex with entire margins, and up to 2 mm in diameter. Catalase-negative. Additional morphological details, cell-wall composition, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus or as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. *Actinomyces howellii* strains exhibit characteristic although not completely identical polypeptide patterns when analyzed by SDS-PAGE which allow clear separation of *Actinomyces howellii* from both *Actinomyces naeslundii* and *Actinomyces denticolens*. Whole-cell agglutination results showed that *Actinomyces naeslundii* and *Actinomyces howellii* were serologically distinct. Immunoblotting revealed some antigenic relationship between *Actinomyces howellii* and *Actinomyces denticolens* on the one hand and *Actinomyces naeslundii* and *Actinomyces viscosus* on the other hand.

Source: oral cavity of cattle, especially dental plaque. Pathogenicity has not been reported. The type strain was isolated from supragingival plaque of dairy cattle.

DNA G+C content (mol%): 66–67 (T_m).

Type strain: Sh 7/4276, ATCC 43323, CCUG 32757, CIP 103127, NCTC 11636.

Sequence accession no. (16S rRNA gene): X80411.

18. **Actinomyces hyovaginalis** Collins, Stubbs, Hommez and Devriese 1993, 472[VP]

hy.o.va.gi.na′lis. Gr. masc. and fem. n. *hys*, *hyos* pig, sow; L. fem. n. *vagina* sheath, vagina; L. masc. suff. *-alis* suffix denoting pertaining to; N.L. masc. adj. *vaginalis* of (pertaining to) the vagina; N.L. masc. adj. *hyovaginalis* pertaining to the vagina of a sow.

The species *Actinomyces hyovaginalis* has been differentiated into two biovars, which were designated the "vaginal" and the "general" biovars, respectively. The "vaginal" biovar resembles "*Actinomyces suis*" Franke (1973) phenotypically for which no type strain exists. Cells of both biovars are predominantly diphtheroidal and the rods are arranged in clusters or V or Y forms; coccoid elements may occur. Colonies of the "vaginal" biovar are flat with outrunning edges, particularly when grown anaerobically or under CO_2 on horse blood agar. Colonies of the "general" biovar are smaller and more convex than those commonly seen in vaginal isolates and the typical outrunning edges of the latter are absent. As demonstrated by 16S rRNA gene sequence similarity and DNA–DNA hybridization values, the two biovars belong to one species although they also differ from each other by a few physiological reactions. Catalase-negative. Additional morphological details, cell-wall composition, and nutrition and growth conditions are as given for the genus or as summarized in Table 8. Physiological and other descriptive or differential characteristics including those differentiating the two biovars are listed in Table 5 and Table 9. The natural habitat of the "vaginal" biovar of *Actinomyces hyovaginalis*

appears to be the porcine genital tract; the natural habitat of the "general" biovar is not known definitely.

Source: purulent vaginal discharge and aborted fetuses of sows ("vaginal" biovar) and various other porcine purulent lesions ("general" biovar). The type strain was isolated from the vagina of a sow.

DNA G+C content (mol%): 63–68 (T_m).

Type strain: BM 1192/5, ATCC 51367, CCUG 35604, CCUG 35715, CIP 103923, DSM 10695, NCIMB 702983 (formerly NCFB 2983).

Sequence accession no. (16S rRNA gene): X69616.

19. **Actinomyces israelii** (Kruse 1896) Lachner-Sandoval 1898, 64[AL], emend. Johnson, Moore, Kaneko and Moore 1990, 279[VP] (*Streptothrix israeli* Kruse 1896, 56; *Discomyces israeli* (Kruse 1896) Gedoelst 1902; *Actinobacterium israeli* (Kruse 1896) Sampietro 1908; Cohnistreptothrix *israeli* (Kruse 1896) Pinoy 1913; *Nocardia israeli* (Kruse 1896) Castellani and Chalmers 1913; *Oospora israeli* (Kruse 1896) Sartory 1920; *Brevistreptothrix israeli* (Kruse 1896) Lignières 1924; *Corynebacterium israeli* (Kruse 1896) Haupt and Zeki 1933; *Proactinomyces israeli* (Kruse 1896) Negroni 1934)

is.ra.e′li.i. N.L. gen. masc. n. *israelii* of Israel, to honor James Israel, a German surgeon, who was one of the original describers of the organism.

Cells frequently present as shorter and longer, branching filaments (Figure 20), but diphtheroidal forms may occur simultaneously or may even predominate. Microcolonies are filamentous, and the most common and characteristic form is the "spider colony" (Figure 30). Mature colonies measure 0.5–2.0 mm in diameter and are predominantly rough with or without central depression. They have been described as molar-tooth-, bread-crumb-, and raspberry-like (Figure 41 and Figure 42), are white to grayish to creamy in color and usually hard and adhering to the medium. In liquid media, they may present as snow ball- or cotton pad-like structures (Figure 56). Catalase-negative. Additional morphological details, ultrastructure, cell-wall composition, nutrition and growth conditions, metabolism, metabolic pathways, and drug sensitivity are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. Although the species *Actinomyces israelii* as currently defined was restricted to the former *Actinomyces israelii* serovar I strains, it appears to be still antigenically heterogeneous (Schaal and Gatzer, 1985). Furthermore, two additional serological types were found among strains fitting the general description of *Actinomyces israelii sensu lato.* As these serological variants differed from typical members of the taxon in a number of physiological characteristics, it remains to be seen whether they constitute new serovars of *Actinomyces israelii sensu stricto* or *Actinomyces gerencseriae* or deserve species rank.

The normal habitat of *Actinomyces israelii* is the oral cavity of man including tonsillar crypts and dental plaque. In humans with healthy gingivae, it could be identified in 6.5% of the samples examined and accounted for 0.4% of the total flora analyzed. In patients with gingivitis and periodontitis, the respective figures were 9.4% and 0.7%. Furthermore, *Actinomyces israelii* may be recovered from the mucosal surfaces of the human intestinal and female genital tracts. *Actinomyces israelii* is one of the principal causative agents of human cervicofacial, thoracic, abdominal, and pelvic actinomycoses. In addition, it may cause eye infections such as lacrimal canaliculitis, conjunctivitis or dacryocystitis and is apparently also etiologically involved in the development of cervicitis and endometritis in women using intrauterine contraceptive devices or vaginal pessaries. Occasionally, *Actinomyces israelii* (or *Actinomyces gerencseriae*) has been reported from animal infections such as actinomycoses in cattle or swine and pyogenic granulomas in a mandrill. However, it is not definite whether these isolates were correctly identified. Sulfur granules are characteristically, but not obligatorily produced in human infections. After intraperitoneal, intravenous, or subcutaneous injection, *Actinomyces israelii* produces abscess formation in a variety of experimental animals including hamsters, mice, and rabbits. The pathological lesions thus induced resemble naturally occurring actinomycoses to a certain extent, but are usually self-limited and not progressive unless at least one typical concomitant organism is added to the challenge injection.

Source (type strain): a human brain abscess.

DNA G+C content (mol%): 63–70 (T_m).

Type strain: ATCC 12102, CCUG 18307, CIP 103259, DSM 43320, JCM 12964, NCTC 12972.

Additional reference strain: ATCC 10048, which differs serologically from the type strain.

Sequence accession no. (16S rRNA gene): X82450.

20. **Actinomyces johnsonii** Henssge, Do, Radford, Gilbert, Clark and Beighton 2009, 515[VP]

john.so′ni.i. N.L. gen. masc. n. *johnsonii* of Johnson, to honor the American molecular biologist John L. Johnson, who undertook extensive studies on the genetic relationships between oral actinomycetes.

The species contains strains previously identified as *Actinomyces naeslundii* serotype WVA 963 or *Actinomyces naeslundii* genospecies WVA 963. Cellular and colonial morphology are similar to those described for *Actinomyces naeslundii* and *Actinomyces oris.* Catalase-negative. Additional morphological details, chemotaxonomic properties, nutrition and growth conditions, and metabolism are as given for the genus and as summarized in Table 6. Physiological and other descriptive or differential characteristics are listed in Table 4 and Table 7. However, morphological and physiological properties usually do not suffice for reliable identification. The latter can be achieved by sequence comparison of partial gene sequences of *atpA* or *metG.* The normal habitat of *Actinomyces johnsonii* is the oral cavity of man. It was found to account for 3.4% of the healthy periodontal flora and was detected in 34.5% of the samples examined. The respective figures for patients with gingivitis and periodontitis were 2.4% and 26.2%. Whether and to what extent *Actinomyces johnsonii* may be present in other human body areas remains to be determined. Although *Actinomyces johnsonii* (*Actinomyces naeslundii* serovar WVA 963) represents a major component of the periodontal flora (the oral biofilm), its contribution

to the development of gingivitis and periodontitis remains uncertain given its relative incidence in human periodontal floras of healthy and diseased individuals (see above). No reliable information is available on the potential role of the organism in invasive human infections. Also, detailed experimental animal studies have apparently not been performed yet.

Source (type strain): gingival crevice of a healthy child.

DNA G+C content (mol%): 67 (T_m).

Type strain: ATCC 49338, CCUG 34287.

Sequence accession no. (16S rRNA gene): EU667411.

21. **Actinomyces marimammalium** Hoyles, Pascual, Falsen, Foster, Grainger and Collins 2001c, 154[VP]

ma.ri.mam.ma′li.um. L. neut. n. *mare*, *maris* sea, ocean; L. fem. n. *mamma* breast, mammary gland; N.L. neut. pl. n. *mammalia* mammals; N.L. gen. pl. n. *marimammalium* of marine mammals.

Cells are straight to slightly curved rods, some of which exhibit branching. Colonies are gray, entire, circular, convex, non-hemolytic and pin-point to 0.5 mm in diameter. Catalase-negative. Additional morphological details, chemotaxonomic markers, nutrition and growth conditions, metabolism, and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. In SDS-PAGE analysis, the *Actinomyces marimammalium* isolates were recovered in a single group which was well separated from all other reference strains examined. The natural habitat is not known. The strains were isolated from multiple organs of a dead male hooded seal, the small intestine of a dead gray seal which had been shot, and from the lung of a harbor porpoise.

Source (type strain): lung, liver, kidney, and mesenteric lymph node of a dead male hooded seal.

DNA G+C content (mol%): 66 (method not reported).

Type strain: M1749/98/1, CCUG 41710, CIP 106509, DSM 15383.

Sequence accession no. (16S rRNA gene): AJ276405.

22. **Actinomyces massiliensis** Renvoise, Raoult and Roux 2009, 541[VP]

mas.si.li.en′sis. L. masc. adj. a *massiliensis* of or belonging to *Massilia*, the old Greek and Roman name for Marseille, where the type strain had been isolated.

Cells are anaerobic, straight rods (0.5–1.7 µm in length and 0.35–0.74 µm in diameter). After 48 h of incubation on sheep blood agar, colonies are pinpoint, circular, white, shiny, and non-hemolytic. Catalase-negative. Additional morphological details, chemotaxonomic markers as well as nutrition and growth conditions are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7.

The natural habitat is not known.

Source (type strain): blood culture of a 38-year-old man with pleuropneumonia.

DNA G+C content (mol%): not reported.

Type strain: 4401292, CSUR P18, CCUG 53522.

Sequence accession no. (16S rRNA gene): EF558367.

23. **Actinomyces meyeri** (Prévot 1938) Cato, Moore, Nygard and Holdeman 1984, 487[VP] (*Actinobacterium meyeri* Prévot 1938, 303)

me.ye′ri. N.L. gen. masc. n. *meyeri* of Meyer, to honor Kurt F. Meyer, a German bacteriologist, who described the organism as a "new anaerobic *Streptothrix* species" in 1911.

Cells grown in peptone-yeast extract-glucose broth supplemented with vitamin K_1, hemin, and Tween 80 are short rods (0.5–0.9 µm by 0.9–3.0 µm) and occur in pairs, short chains, or clumps. Terminal swellings are present occasionally, and branching may be difficult to demonstrate. Microcolonies are smooth and non-filamentous resembling those of *Actinomyces odontolyticus*. Mature surface colonies on supplemented BHIA incubated anaerobically are pinpoint to 1 mm in diameter, circular, flat to convex, translucent to opaque and white, with shiny, smooth surfaces, and entire margins. They may be α- or non-hemolytic. Growth in air with 5% CO_2 added is very slight or absent. *Actinomyces meyeri* has an absolute requirement for vitamin K_1, and growth is greatly stimulated by 0.02% Tween 80 and by a fermentable carbohydrate. Addition of serum may also stimulate growth. Catalase-negative. Additional morphological details, nutrition and growth conditions, metabolism and metabolic pathways, and drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The patterns of soluble cellular proteins as determined by polyacrylamide gel electrophoresis indicate that the strains tested so far represent a homogeneous taxon. Most of the isolates studied gave a positive fluorescent antibody reaction with monovalent FITC-conjugate prepared against strain ATCC 33972. Cross-reactions have not been observed with conjugates to *Actinomyces gerencseriae*, *Actinomyces israelii*, *Actinomyces johnsonii*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, serovars I and II, and *Actinomyces oris*. However, as several isolates of *Actinomyces meyeri* did not react with the antiserum to strain ATCC 33972, there may exist additional serovars of the species. The principal natural habitat of *Actinomyces meyeri* is the human periodontal sulcus. In addition, the organism has been isolated frequently from brain abscesses and pleural fluid and less often from abscesses of the cervicofacial area, hips, hands, feet and spleen and from bite wounds.

Source (type strain): Purulent human pleurisy.

DNA G+C content (mol%): 64–67 (spectrometry/chromatography).

Type strain: Prévot 2477B, ATCC 35568, CCUG 21024, CIP 103148, DSM 20733, LMG 16161, VPI 8617.

Sequence accession no. (16S rRNA gene): X82451.

24. **Actinomyces naeslundii** Thompson and Lovestedt 1951, 175[AL], emend. Henssge, Do, Radford, Gilbert, Clark and Beighton 2009, 516[VP]

na.es.lun′di.i. N.L. gen. masc. n. *naeslundii* of Naeslund, to honor Carl Naeslund from Sweden, who first described this organism in some detail, but did not give it a species epithet.

The species contains strains previously identified as *Actinomyces naeslundii* serovar I, also known as *Actinomyces*

naeslundii genospecies 1. Cells of *Actinomyces naeslundii* are usually diphtheroidal showing some branching (Figure 23) and/or arrangement in Y, V, or T forms. Microcolonies may be highly filamentous (Figure 32), but may also show the result of early fragmentation leading to less to non-filamentous colony forms. Mature colonies are either smooth or finely granular (Figure 46) and circular, or they may show branching filaments in the periphery of the colony (Figure 47) or even present as a molar-tooth colony (Figure 48). Their diameter may be greater than 2 mm. Catalase-negative. Additional morphological details, ultrastructure, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. *Actinomyces naeslundii* can reliably be differentiated from the closely related species of the former *Actinomyces naeslundii/Actinomyces viscosus* complex on the basis of sequence comparison of partial gene sequences of *atpA* and *metG*. A clear-cut distinction from *Actinomyces oris* and *Actinomyces johnsonii* is as yet not possible by phenotypic testing. After emendation of the species, it appears to be serologically homogeneous. The normal habitat of *Actinomyces naeslundii* is the oral cavity of man including tonsillar crypts and dental plaque. It was found to account for 7.6% of the human healthy periodontal flora and occurred in 54.6% of the samples examined. The respective figures for patients with gingivitis and periodontitis were 2.7% and 30.7%. The species may also be detected in cervicovaginal secretions from women using and not using IUCDs. Human infections due to *Actinomyces naeslundii* most frequently present as cervicofacial, thoracic, or abdominal actinomycotic lesions clinically indistinguishable from those produced by *Actinomyces israelii* or *Actinomyces gerencseriae* although some of the reports blaming *Actinomyces naeslundii* as causative agent might have been biased by mixed infections with *Actinomyces israelii* or *Actinomyces gerencseriae* or by contamination of the specimen from mucosal secretions. However, eye infections (e.g., lacrimal canaliculitis) and infections of the female genital tract as well as gallbladder infections, pelvic infections, mediastinal actinomycosis, a disseminated infection in a mentally retarded child, a recurring empyema of the knee joint, and infections of a total knee arthroplasty and a hip prosthesis have also been reported. Furthermore, the species obviously plays an important role in the complex etiology and pathogenesis of caries and periodontitis. After parenteral inoculation, *Actinomyces naeslundii* was found to cause abscess formation in experimental animals. After oral inoculation, the organism is apparently able to initiate periodontitis with alveolar bone loss and/or fissure lesions in hamsters and conventional as well as gnotobiotic rats.

Source (type strain): human sinus secretions.

DNA G+C content (mol%): 63 (T_m).

Type strain: ATCC 12104, CCUG 2238, CCUG 18310, CCUG 32832, CCUG 35333, CDC W826, CIP 103128, DSM 43013, JCM 8349, NCTC 10301.

Sequence accession no. (16S rRNA gene): X81062.

25. **Actinomyces nasicola** Hall, Collins, Lawson, Falsen and Duerden 2003d, 1447[VP]

na.si′co.la. L. masc. n. *nasus, nasi* nose; L. masc. suff. *-cola* from L. masc. n. *incola* inhabitant, dweller; N.L. masc. n. *nasicola* inhabitant of the nose, referring to the body site from which the type strain had been isolated.

Cells are short, diphtheroid-shaped rods; some branching and coccoid forms occur. After 48 h of anaerobic incubation on Fastidious Anaerobe Agar, colonies are pinpoint, white or gray, opaque, shiny, entire, and convex. Catalase-negative. Additional morphological details, chemotaxonomic markers, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The organism produced a unique 16S rDNA restriction pattern with *Hae*III and *Hpa*II that was distinct from the profiles of over 400 *Actinomyces* strains. The natural habitat is not known. The single strain encountered so far was isolated from a nasal antrum washout.

Source (type strain): nasal antrum aspirate.

DNA G+C content (mol%): 66.5 (HPLC).

Type strain: R2014, CCUG 46092, CIP 107668, DSM 19116.

Sequence accession no. (16S rRNA gene): AJ508455.

26. **Actinomyces neuii subsp. neuii** and **Actinomyces neuii subsp. anitratus** Funke, Stubbs, von Graevenitz and Collins 1994, 170[VP]

neu′i.i. N.L. gen. masc. n. *neuii* of Neu, to honor Harold Neu, an authority in antimicrobial chemotherapy and infectious diseases.

DNA G+C content (mol%): 55–58 (T_m).

26a. **Actinomyces neuii subsp. neuii**

Cells are predominantly diphtheroidal and rods are arranged in clusters or V or Y forms; coccobacillary elements may occur. Colonies are circular, smooth, convex, opaque, more white than creamy in color, and with entire edges, and 0.5–1.5 mm in diameter after 48 h of incubation. α-Hemolysis is observed on sheep blood agar for most strains. Catalase-positive. Nitrate is reduced to nitrite.

Source (type strain): human blood.

Type strain: 97/90, ATCC 51847, CCUG 32252, CIP 104015, DSM 8576.

Sequence accession no. (*16S rRNA gene):* AM084228 (ATCC 51847).

26b. **Actinomyces neuii subsp. anitratus**

a.ni.tra′tus. Gr. pref. *a-* not; N.L. n. *nitras*, *nitratis* nitrate; L. masc. suff. *-atus* suffix used in adjectives meaning provided with; N.L. masc. adj. *anitratus* intended to mean not reducing nitrate.

The morphological characteristics are similar to those of the subspecies *neuii*, except that *Actinomyces neuii* subsp. *anitratus* is non-hemolytic. Catalase-positive. Nitrate is **not** reduced to nitrite. Additional morphological details, chemotaxonomic characteristics and nutrition and growth conditions for both subspecies are as given for the genus or

as summarized in Table 6. Physiological and other descriptive or differential characteristics including those suitable for differentiating the two subspecies from one another are listed in Table 4 and Table 7. Strains of both subspecies of *Actinomyces neuii* have mainly been isolated from human abscesses in association with mixed anaerobic flora as well as from blood cultures. The natural habitat of the subspecies of *Actinomyces neuii* is not definitely known.

Source (type strain): human mammary hematoma.

Type strain: 50/90, ATCC 51849, CCUG 32253, CIP 104016, DSM 8577, LMG 14788.

Sequence accession no. (*16S rRNA gene*)*:* AM084229 (ATCC 51849).

27. **Actinomyces odontolyticus** Batty 1958, 455[AL]

o.don.to.ly′ti.cus. Gr. masc. n. *odous*, *-ontos* tooth; N.L. masc. adj. *lyticus* (from Gr. masc. adj. *lutikos*) able to loosen, able to dissolve; N.L. masc. adj. *odontolyticus* tooth-dissolving.

Cells of *Actinomyces odontolyticus* are usually diphtheroidal (Figure 26), but may also be coccobacillary (Figure 27). In very early growth stages, cells may show signs of budding (Figure 57). Microcolonies are non-filamentous (Figure 36) and mature colonies are 1–2 mm in size, smooth, with an entire to irregular edge and granular structures inside the colony (Figure 53 and Figure 54). When grown on BHIA, the colonies are opaque to translucent and white to gray-white. After 5–10 d of incubation on blood agar, however, the colonies usually become deep red. This pigmentation may be seen on plates incubated anaerobically or it may become apparent after the cultures have been left standing in air at room temperature following primary anaerobic incubation. Catalase-negative. Additional morphological details, ultrastructure, cell-wall composition, nutrition and growth conditions, metabolism and metabolic pathways, and drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive or differential characteristics are listed in Table 4 and Table 7. Two serovars of *Actinomyces odontolyticus* have been described which show only low-grade cross-reactivity between each other. However, considerable cross-reactions appear to occur between *Actinomyces odontolyticus* serovar II strains and *Arcanobacterium pyogenes*. The natural habitat of *Actinomyces odontolyticus* is the oral cavity of man, in particular dental plaque and calculus. Progressive actinomycotic infections of this organism in man have been reported, but are apparently rare. More frequently, *Actinomyces odontolyticus* is etiologically involved in the development of eye infections such as lacrimal canaliculitis and possibly also of periodontitis and caries. Primarily, it had been isolated from deep carious lesions in man. Naturally occurring animal infections by *Actinomyces odontolyticus* have only been reported twice, from one dog and one cat. Experimental animal infections were produced with varying success.

Source (type strain): a deep carious lesion in man.

DNA G+C content (mol%): 61–62 (T_m).

Type strain: ATCC 17929, CCUG 20536, CIP 101124, DSM 43760, JCM 14871, LMG 18080, NCTC 9935.

Sequence accession no. (16S rRNA gene): AJ234040.

28. **Actinomyces oricola** Hall, Collins, Hutson, Inganäs, Falsen and Duerden 2003c, 1517[VP]

o.ri′co.la. L. neut. n. *os*, *oris* mouth; L. masc. suff. *-cola* from L. masc. n. *incola* inhabitant; N.L. masc. n. *oricola* inhabitant of the mouth.

Cells are rod-shaped and some of them display branching; filaments may be observed. After 48 h of anaerobic incubation on Fastidious Anaerobe Agar with 5% horse blood, colonies are pinpoint, breadcrumb-like, and nonhemolytic. Catalase-negative. Additional morphological details, chemotaxonomic markers, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. The natural habitat is not known.

Source (type strain): a human dental abscess.

DNA G+C content (mol%): not reported.

Type strain: R5292, CCUG 46090, CIP 107639, DSM 17234.

Sequence accession no. (16S rRNA gene): AJ507295.

29. **Actinomyces oris** Henssge, Do, Radford, Gilbert, Clark and Beighton 2009, 514[VP]

o′ris. L. neut. n. *os* mouth; L. gen. n. *oris* of the mouth.

The species comprises strains previously identified as *Actinomyces naeslundii* serovars II, III, and NV as well as *Actinomyces viscosus* serovar II and has also been known as *Actinomyces naeslundii* genospecies 2. Cellular and colonial morphology resemble those described for *Actinomyces naeslundii* (Figure 49) although less filamentous forms predominate (Figure 33 and Figure 50). Quite often, smooth, entire, and soft colonies are seen (Figure 45) which resemble those of propionibacteria. Catalase may or may not be produced. Additional morphological details, chemotaxonomic properties, nutrition and growth conditions, and metabolism are as given for the genus and as summarized in Table 6. Physiological and other descriptive or differential characteristics are listed in Table 4 and Table 7. However, morphological and physiological properties usually do not suffice for reliable identification. The latter can be achieved by sequence comparison of partial gene sequences of *atpA* or *metG*. As the species *Actinomyces oris* contains strains formerly classified as *Actinomyces naeslundii* serovars II, III, and NV and *Actinomyces viscosus* serovar II, it must be antigenically heterogeneous, but the definite antigenic structure of the new species remains to be described. The normal habitat of *Actinomyces oris* is the oral cavity of man. It accounts for 8.3% of the healthy periodontal flora and was detected in 79.8% of the samples examined. The respective figures for patients with gingivitis and periodontitis were 8.2% and 77.4%. *Actinomyces oris* has obviously also been recovered from cervicovaginal secretions of women with or without IUCDs and from the uninfected conjunctiva and/or cornea of man. Occasionally, *Actinomyces oris* (*Actinomyces viscosus* serovar II) has been isolated from cervicofacial and abdominal cases of human actinomycoses and at least in some of these cases, *Actinomyces oris* appeared to be the primary pathogen. Furthermore, the species may be involved

in the etiology of lacrimal canaliculitis and other eye infections and possibly also in the etiology of cervicitis and endometritis of women using IUCDs. Among the members of the genus *Actinomyces*, *Actinomyces oris* represents a species whose contribution to the development of caries and periodontitis has been established convincingly. Experimental animal studies using *Actinomyces viscosus sensu lato* strains need to be re-evaluated in light of modern taxonomic revisions.

Source (type strain): human sputum.

DNA G+C content (mol%): 66 (T_m).

Type strain: ATCC 27044, CCUG 34288.

Sequence accession no. (16S rRNA gene): EU667403.

30. **Actinomyces radicidentis** Collins, Hoyles, Kalfas, Sundquist, Monsen, Nikolaitchouk and Falsen 2001, 1[VP] (Effective publication: Collins, Hoyles, Kalfas, Sundquist, Monsen, Nikolaitchouk and Falsen 2000, 3402.)

ra.di.ci.den′tis. L. fem. n. *radix*, *radicis* root; L. masc. n. *dens*, *dentis* tooth; N.L. gen. n. *radicidentis* of the root of the tooth.

Cells are coccoid. Catalase-positive. Additional morphological details, nutrition and growth conditions and metabolic activities are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. In SDS-PAGE analysis the two isolates of *Actinomyces radicidentis* dealt with in the original description clustered together and were clearly separated from other *Actinomycetaceae*. The natural habitat is not known. The two strains were isolated from infected root canals of human teeth.

Source (type strain): infected root canal of the upper right canine of an 80-year-old woman who had suffered from persistent symptoms after conventional root canal treatment.

DNA G+C content (mol%): not reported.

Type strain: CCUG 36733, CIP 106352, DSM 15433.

Sequence accession no. (16S rRNA gene): AJ251986.

31. **Actinomyces radingae** Wüst, Stubbs, Weiss, Funke and Collins 1995b, 619[VP] (Effective publication: Wüst, Stubbs, Weiss, Funke and Collins 1995a, 80.), emend. Vandamme, Falsen, Vancanneyt, Van Esbroek, Van de Merwe, Bergmans, Schouls and Sabbe 1998, 509[VP]

ra.din′ga.e. M.L. fem. n. *Radinga* the Latin name for Reading, UK; M.L. fem. gen. n. *radingae* of (pertaining to) Reading.

Cells are coccoid rods (0.65 µm in diameter and 1 µm long). Pseudobranching is rare.

After 48 h of incubation on sheep blood agar in a 5% CO_2 atmosphere, colonies are small, gray, convex, circular, and opaque with a glistening surface, an entire edge, and a butyrous consistency. A hemolytic zone appears slowly and mostly starts with α-hemolysis. Catalase-negative. Additional morphological details, cell-wall composition and other chemotaxonomic properties, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. *Actinomyces radingae* strains have chiefly been isolated from human mixed infections including otitis, empyema, pilonidal cyst, perianal abscesses, and decubitus ulcers. The isolates have usually been found to be associated with anaerobes, "*milleri*" streptococci, enterococci, and Gram-stain-negative rod-shaped bacteria. The natural habitat is not definitely known.

Source (type strain): a human perianal abscess.

DNA G+C content (mol%): 60 (T_m).

Type strain: APL1, ATCC 51856, CCUG 32394, (CCUG 34270), CIP 105358, DSM 9169, LMG 15960.

Sequence accession no. (16S rRNA gene): X78719.

32. **Actinomyces ruminicola** An, Cai and Dong 2006, 2045[VP]

ru.mi.ni′co.la. L. n. *rumen*, *ruminis* first stomach of ruminants, rumen; L. masc. suffix *-cola* from L. masc. n. *incola* inhabitant; N.L. masc. n. *ruminicola* inhabitant of rumen from which the type strain had been isolated.

Cells are straight strictly anaerobic rods (0.5–1.0 µm in diameter and 2.5–4.0 µm in length). Colonies on peptone-yeast extract-glucose agar with 15% rumen fluid (PYGR agar) are circular, slightly convex, and white and reach approximately 0.5–0.8 mm in diameter after 48 h of anaerobic incubation at 46°C. The organism grows between 20 and 55°C with optimum growth at 46°C. Catalase-negative. Additional morphological details, ultrastructure, chemotaxonomic markers, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. The natural habitat appears to be cattle rumen. Pathogenicity has not been reported.

Source (type strain): cattle rumen.

DNA G+C content (mol%): not reported.

Type strain: B71, JCM 13352, CGMCC 1.5030.

Sequence accession no. (16S rRNA gene): DQ072005.

33. **Actinomyces slackii** Dent and Williams 1986, 394[VP]

slac′ki.i. N.L. gen. masc. n. *slackii* of Slack, to honor John M. Slack, an expert on *Actinomyces* and actinomycosis.

Cells are short rods (0.56 µm by 0.8 µm). Colonies on horse blood agar after 3–5 d of incubation are white, smooth, shiny, translucent, and convex, have entire margins and measure up to 2 mm in diameter. Catalase-positive. Additional morphological details, cell-wall composition, nutrition and growth conditions, and metabolism and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive or differential characteristics are listed in Table 5 and Table 9. The patterns of polypeptides produced by SDS-PAGE are homogeneous within the species, but quite distinct from those of *Actinomyces howellii*, *Actinomyces viscosus*, and *Actinomyces naeslundii*. *Actinomyces slackii* has been isolated from the oral cavities of a number of individual dairy cattle, in particular from dental plaque. Pathogenicity has not been reported.

Source: oral cavity of dairy cattle, in particular dental plaque.

DNA G+C content (mol%): 65–67 (T_m).

Type strain: Sh 13/4563, ATCC 49928, CCUG 32792, CIP 103130, NCTC 11923.

Sequence accession no. (16S rRNA gene): AJ234066.

34. **Actinomyces suimastitidis** Hoyles, Falsen, Holmström, Persson, Sjödén and Collins 2001a, 1326[VP]

su.i.mas.ti'ti.dis. L. fem. n. *sus*, *suis* pig; N.L. n. *mastitis*, *-idis* inflammation of the milk gland; N.L. gen. n. *suimastitidis* of porcine mastitis.

Cells are straight to slightly curved rods. Catalase-negative. Additional morphological details as well as nutrition and growth conditions are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. In SDS-PAGE analysis, the *Actinomyces suimastitidis* isolate was found to be different from all *Actinomyces* species described until 2001. The natural habitat is not known. The single strain of the species encountered so far was isolated from pig mastitis, but its pathogenic potential has not been proven.

Source (type strain): mammary gland of a sow with chronic granulomatous mastitis.

DNA G+C content (mol%): not reported.

Type strain: CCUG 39276, CIP 106779, DSM 15538.

Sequence accession no. (16S rRNA gene): AJ277385.

35. **Actinomyces timonensis** Renvoise, Raoult and Roux 2010, 1520[VP]

ti.mo.nen'sis. N.L. masc. adj. *timonensis* of or pertaining to the Hôpital de la Timone, the hospital in Marseille, France, where the type strain was isolated.

Cells are Gram-stain-positive, straight rods. As estimated by electron microscopy, they measure 1.0–3.2 µm in length and 0.3–0.5 µm in diameter. Catalase- and oxidase-negative. Optimal growth occurs under anaerobic conditions at 37°C; growth was also obtained at 25°C and 30°C, but not at 44°C, and occurred in an atmosphere of 5% CO_2 as well as under "microaerophilic" and anaerobic conditions, but was weak in air. After 48 h of incubation on sheep blood agar, colonies are pinpoint, circular, white, dry, embedded in the agar medium, and α-hemolytic. When using API 50 CH strips, after 24 h of incubation, acid is produced from D-galactose, D-glucose, D-fructose, inositol, D-mannitol, *N*-acetylglucosamine, esculin, ferric citrate, salicin, maltose, lactose, melibiose, sucrose, trehalose, melezitose, and raffinose. After 48 h of incubation, acid is also produced from glycerol, D-ribose, D-mannose, and glycogen and weakly from D-arabitol. Acid is not produced from erythritol, D- and L-arabinose, D- and L-xylose, methyl-β-D-xylopyranoside, L-sorbose, L-rhamnose, dulcitol, D-sorbitol, methyl-α-D-mannopyranoside, methyl-α-D-glucopyranoside, amygdalin, cellobiose, inulin, starch, xylitol, gentiobiose, turanose, D-lyxose, D-tagatose, D- and L-fucose, L-arabitol, potassium gluconate, potassium 2-ketogluconate, or potassium 5-ketogluconate. After 24 h of incubation, acid production from arbutin is variable. After 48 h of incubation, acid production is variable from D-adonitol and arbutin. Using the API ZYM system, leucine arylamidase activity is detected, but valine arylamidase, β-galactosidase, α-glucosidase, alkaline phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are not. Using the API Rapid ID32A system, β-glucosidase, proline arylamidase, phenylalanine arylamidase, leucine arylamidase, and tyrosine arylamidase are detected. Variable reactions are obtained for α-glucosidase, mannose fermentation, and raffinose fermentation. Urease, arginine dihydrolase, α-galactosidase, β-galactosidase-6-phosphate, β-galactosidase, α-arabinosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, glutamic acid decarboxylose, α-fucosidase, nitrate reduction, indole production, alkaline phosphatase, arginine arylamidase, leucyl glycine arylamidase, pyroglutamic acid arylamidase, alanine arylamidase, glycine arylamidase, histidine arylamidase, glutamyl glutamic acid arylamidase, and serine arylamidase reactions were negative. The type strain was found to be susceptible to penicillin G, amoxicillin plus clavulanic acid, cefotetan, vancomycin, and imipenem, but resistant to metronidazole. In the phylogenetic tree produced from 16S rRNA gene sequences by the neighbor-joining method *Actinomyces timonensis* clustered close to *Actinomyces denticolens* so that it appears to be a member of the *Actinomyces* core cluster 1. MALDI-TOF MS analysis confirmed that *Actinomyces timonensis* is a novel *Actinomyces* species. The natural habitat is not known.

Source (type strain): a clinical osteo-articular sample from a 13-year-old girl.

DNA G+C content (mol%): not reported.

Type strain: 7400942, CSUR P35, CCUG 55928.

Sequence accession no. (16S rRNA gene): EU484334.

36. **Actinomyces turicensis** Wüst, Stubbs, Weiss, Funke and Collins 1995b, 619[VP] (Effective publication: Wüst, Stubbs, Weiss, Funke and Collins 1995a, 80.), emend. Vandamme, Falsen, Vancanneyt, Van Esbroek, Van de Merwe, Bergmans, Schouls and Sabbe 1998, 509)

tu.ri.cen'sis. L. masc. adj. *turicensis* of or pertaining to *Turicum* (Zürich) referring to the place where the type strain had been isolated.

Cells are straight and slightly curved, Gram-stain-variable rods (0.5–0.8 µm in diameter and 1.3–4.0 µm in length) with some (pseudo)branching and a beaded appearance. A few club-shaped cells may be present. After 48 h of incubation on sheep blood agar in air with 5% CO_2, colonies are small, gray, convex, circular, and opaque with a glistening surface, an entire edge and a butyrous consistency. A small hemolytic zone is more visible when strains are grown under CO_2 enrichment or anaerobically. Catalase-negative. Additional morphological details, cell-wall composition and other chemotaxonomic properties, nutrition and growth conditions, metabolism and metabolic pathways as well as drug susceptibility are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. *Actinomyces turicensis* strains have chiefly been isolated from human mixed infections including otitis, empyema, pilonidal cyst, perianal abscesses, and

decubitus ulcers. The isolates were usually found to be associated with anaerobes, "*milleri*" streptococci, enterococci, and Gram-stain-negative rod-shaped bacteria. The natural habitat is not definitely known.

Source (type strain): human perianal abscess.

DNA G+C content (mol%): 57.5 (T_m).

Type strain: APL10, ATCC 51857, CCUG 32401, CCUG 34269, CIP 105357, DSM 9168, LMG 15961.

Sequence accession no. (16S rRNA gene): X78720.

37. **Actinomyces urogenitalis** Nikolaitchouk, Hoyles, Falsen, Grainger and Collins 2000, 1653[VP]

u.ro.ge.ni.ta′lis. Gr. n. *ouron* urine; L. adj. *genitalis* belonging to the genital system or progenitive tract; N.L. masc. adj. *urogenitalis* belonging to the urogenital tract.

Cells are straight to slightly curved rods. Catalase-negative. Additional morphological details, nutrition and growth conditions, and metabolic activities are as given for the genus and as summarized in Table 6. Physiological and other descriptive and differential characteristics are listed in Table 4 and Table 7. *Actinomyces urogenitalis* strains formed a homogeneous group in the SDS-PAGE analysis that was distinct from all other *Actinomyces* species described until 2000. The natural habitat is not known.

Source: urine, vaginal secretions, and the human urethra. The type strain was isolated from vaginal secretions of a 33-year-old woman with abnormal vaginal discharge.

DNA G+C content (mol%): 61 (T_m).

Type strain: CCUG 38702, CIP 106421, DSM 15434.

Sequence accession no. (16S rRNA gene): AJ243791.

38. **Actinomyces vaccimaxillae** Hall, Collins, Hutson, Inganäs, Falsen and Duerden 2003a, 604[VP]

vac.ci.ma.xil′la.e. L. fem. n. *vacca* cow; L. fem. n. *maxilla* the jaw; N.L. gen. n. *vaccimaxillae* of a cow's jaw.

Cells are coccobacillary to short diphtheroidal rods. After 48 h of anaerobic incubation on Fastidious Anaerobe Agar with 5% horse blood, colonies are <1 mm in diameter, convex, smooth, entire-edged, opaque white, and non-hemolytic. Catalase-negative. Additional morphological details, nutrition and growth conditions as well as metabolism and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive and differential characteristics are listed in Table 5 and Table 9. The natural habitat is not known.

Source (type strain): a purulent lesion in the jaw of a cow.

DNA G+C content (mol%): not reported.

Type strain: R10176, CCUG 46091, CIP 107423, DSM 15804.

Sequence accession no. (16S rRNA gene): AJ427451.

39. **Actinomyces viscosus** (Howell, Jordan, Georg and Pine 1965) Georg, Pine and Gerencser 1969, 292[AL] (*Odontomyces viscosus* Howell, Jordan, Georg and Pine 1965, 65)

vis.co′sus. L. masc. adj. *viscosus* sticky.

After the taxonomic revision of the *Actinomyces naeslundii/ Actinomyces viscosus* complex, the species only contains the so-called hamster strains of the former *Actinomyces viscosus* taxon, which have also been known as *Actinomyces viscosus* serovar I. Cells from broth cultures present as dense clumps of long Gram-stain-positive filaments which vary from finely beaded or stippled thread-like forms to solidly stained, slightly clavate structures. Branching is frequently seen. Growth on BHIA in air without added CO_2 is usually negligible or very poor. However, when plates are incubated in air plus 5% CO_2, growth is rapid and profuse. Microcolonies under such growth conditions at about 12 h of incubation are composed of branched, non-septate filaments (1 µm in diameter), which rapidly undergo septation and angular branching to produce diphtheroidal cells. Mature colonies develop within 2–3 d and vary from 0.5 to 5.0 mm in diameter. They are usually round, strongly convex to heaped, smooth, granular, often with an eccentric pit, cream to white, and dry to viscous in consistency (Figure 34). Occasionally, especially after serial transfer, colonies may become round, entire, low convex, smooth, transparent with an optically dark central "core" visible in transmitted light producing an appearance similar to that of propionibacteria. Catalase-positive. Additional morphological details, ultrastructure, cell-wall composition, nutrition and growth conditions, and metabolism and metabolic pathways are as given for the genus and as summarized in Table 8. Physiological and other descriptive or differential characteristics are listed in Table 5 and Table 9. As morphological and physiological properties may not suffice to reliably identify *Actinomyces viscosus* and differentiate it from *Actinomyces naeslundii*, *Actinomyces oris*, and *Actinomyces johnsonii*, serology can help in identification because cross-reactions with the above group of actinomycetes were found to be weak. *Actinomyces viscosus* has been isolated from subgingival plaque of hamsters and cervical plaque of rats. Thus, the oral cavity of these (and other?) animals appears to be the natural habitat of this species. Bacteria named *Actinomyces viscosus* have also been reported as the causative agents of animal diseases. These included actinomycosis-like lesions in swine, cats, and dogs. However, it remains to be proven whether all of these infections were really due to *Actinomyces viscosus* as currently defined. In contrast, periodontal disease spontaneously occurring in hamsters can be accepted as a disease definitely caused by *Actinomyces viscosus*.

Experimental infections have been produced in mice and hamsters. After oral inoculation, the organism produced periodontitis and/or caries in hamsters as well as in conventional and gnotobiotic rats.

Source (type strain): periodontitis in a hamster.

DNA G+C content (mol%): 59–63 (T_m).

Type strain: ATCC 15987, CCUG 14476, CIP 103147, DSM 43327, JCM 8353, NCTC 10951.

Sequence accession no. (16S rRNA gene): X82453.

Species *incertae sedis*

a. **"Actinomyces houstonensis"** Clarridge and Zhang 2002, 3448

hous.to.nen′sis. N.L. masc. adj. *houstonensis* of or pertaining to Houston, where the organism was described.

Cells are Gram-stain-positive, pleomorphic rods, which have a tendency to form half circles. Colonies on sheep blood agar after 48 h of incubation at 36°C are α-hemolytic, gray, and 0.2 mm in diameter. Growth is equal in air with added CO_2 and under anaerobic conditions. Catalase-negative. Esculin, urea, and gelatin are not hydrolyzed. Nitrate is reduced to nitrite. α-Glucosidase, leucyl-glycine arylamidase, glycine arylamidase, proline arylamidase, phenylalanine arylamidase, arginine arylamidase, and serine arylamidase are produced, but not alkaline phosphatase, pyrrolidonyl arylamidase, and indole. Acid is produced from glucose and sucrose, but not from xylose. All three strains of the species encountered so far originated from serious human subcutaneous abscesses requiring drainage. The natural habitat is not known.

DNA G+C content (mol%): not reported.

Type strain: Houston VAMC strain 3971 was isolated from an abscess from the back of a patient. The strain has not been deposited in one of the international culture collections. The species designation has also not appeared on a Validation List in the IJSEM.

b. **"Actinomyces suis"** Franke 1973, 123 (Not *Actinomyces suis* Gasperini 1892, 183, *Actinomyces suis* Grässer 1957, 148, or *Actinobaculum* (*Eubacterium*, *Actinomyces*) *suis* Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 901, but phenotypically related to *Actinomyces hyovaginalis* Collins, Stubbs, Hommez and Devriese 1993, 472)

su′is. L. masc. and fem. n. *sus, suis* pig, hog; L. gen. n. *suis* of the hog.

Cells are predominantly diphtheroidal and may be arranged in clusters or in V, Y, or T forms. Coccoid elements as well as branched filaments may also occur. Microcolonies may be filamentous, but entire-edged and granular or smooth forms may also be seen. Mature colonies are up to 2 mm in diameter, opaque and raised, and may have entire, undulate, or filamentous margins. Catalase-negative. Growth at 36±1°C is good in air with added CO_2 and anaerobically with and without CO_2. Aerobic growth without CO_2 is weak. Nitrate is reduced to nitrite, gelatin is not liquefied, and indole is not produced. Acid is produced from fructose, galactose, glucose, *myo*-inositol, inulin, lactose, maltose, mannose, raffinose, salicin, starch, sucrose, and trehalose, but not from L-arabinose, rhamnose, sorbitol, and D-xylose. Acid production is variable from adonitol, glycerol, mannitol, and ribose. Using an agar gel precipitation procedure, all of the "*Actinomyces suis*" isolates tested appeared to be serologically homogeneous, but differed clearly from other *Actinomyces* species. Only low-titered cross-reactions were observed with *Actinomyces israelii sensu lato*, *Actinomyces naeslundii sensu lato*, and *Propionibacterium propionicum*. The natural habitat of "*Actinomyces suis*" is not known. The organisms have been isolated from actinomycosis of the mammary gland of swine. The taxonomic and nomenclatural problems associated with "*Actinomyces suis*" have been discussed in the taxonomy section of this chapter.

DNA G+C content (mol%): not reported.

Type strain: none designated or deposited.

Genus II. **Actinobaculum** Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 902[VP]

Paul A. Lawson

Ac.ti.no.ba′cu.lum. Gr. n. *actis*, *actinos* ray; L. neut. n. *baculum* rod, stick; N.L. neut. n. *Actinobaculum* ray stick.

On blood agar, **cells are straight to slightly curved rods, some of which exhibit branching. Cells are Gram-stain-positive, not acid-fast, and nonmotile and do not form spores. Anaerobic or facultatively anaerobic. Catalase-negative.** Acid may or may not be produced from glucose. **The major end product of glucose and/or maltose metabolism is acetate or lactate.** Esculin and gelatin are not hydrolyzed. Nitrate is not reduced to nitrite. Acetoin is not produced. **The cell-wall murein type is type A5a** (L-Lys–L-Ala–Lys–D-Glu or L-Lys–Lys–D-Glu). The major long-chain cellular fatty acids are straight-chain saturated and monounsaturated components.

DNA G+C content (mol%): 55–57 (T_m).

Type species: **Actinobaculum suis** (Wegienek and Reddy 1982) Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 902[VP].

Further descriptive information

Grows on 5% (v/v) sheep or horse blood. Cells are straight to slightly curved. Strains can be isolated on a variety of rich agar-containing media (such as heart infusion agar) supplemented with blood. Strains grow at 37°C in a 5% CO_2 atmosphere or under anaerobic conditions although *Actinobaculum suis* appears to be the only species that prefers anaerobic growth conditions. None of the species produce acid from lactose, mannitol, melibiose, melezitose, raffinose, or sorbitol.

The cell-wall murein of *Actinobaculum* is type A5a. *Actinobaculum suis* contains L-Lys–L-Ala–Lys–D-Glu and *Actinobaculum schaali* L-Lys–Lys–D-Glu (see Schleifer and Kandler, 1972, for nomenclature; Lawson et al., 1997). The murein type for *Actinobaculum urinale* has not been determined.

Actinobaculum species have been recovered from a variety of human and animal sources. *Actinobaculum massiliense*, *Actinobaculum schaalii*, and *Actinobaculum urinale* have been isolated from a number of human clinical sources that include blood (Clarridge and Zhang, 2002; Fendukly and Osterman, 2005; Lawson et al., 1997) and urine (Greub and Raoult, 2002; Hall et al., 2003b). *Actinobaculum suis* has been isolated from several animal sources (Walker and MacLachlan, 1989; Wegienek and Reddy, 1982; Woldemeskel et al., 2002; Yamini and Slocombe, 1988).

Isolation procedures

Strains can be isolated on a variety of rich agar-containing media (such as heart infusion agar) supplemented with 5% (v/v) animal blood (sheep or horse). Strains grow at 37°C in a 5% CO_2 atmosphere or under anaerobic conditions. There is no information on enrichment or selective media for this genus.

Maintenance procedures

Strains can be maintained on agar media (such as heart infusion or Columbia agar) supplemented with blood (5% v/v). Strains grow in brain heart infusion broth supplemented with 5% (v/v) serum. For long-term preservation, strains can either be stored at –70°C on cryogenic beads or lyophilized.

Taxonomic comments

The genus *Actinobaculum* was proposed by Lawson et al. (1997) to accommodate bacterial strains that had previously been assigned to various other genera and that were named "*Actinobaculum suis*", together with *Actinomyces*-like isolates from human clinical specimens. The genus forms a distinct subline, related to but distinct from the genera *Actinomyces*, *Arcanobacterium*, and *Mobiluncus* (Figure 58). Currently, three species, *Actinobaculum*

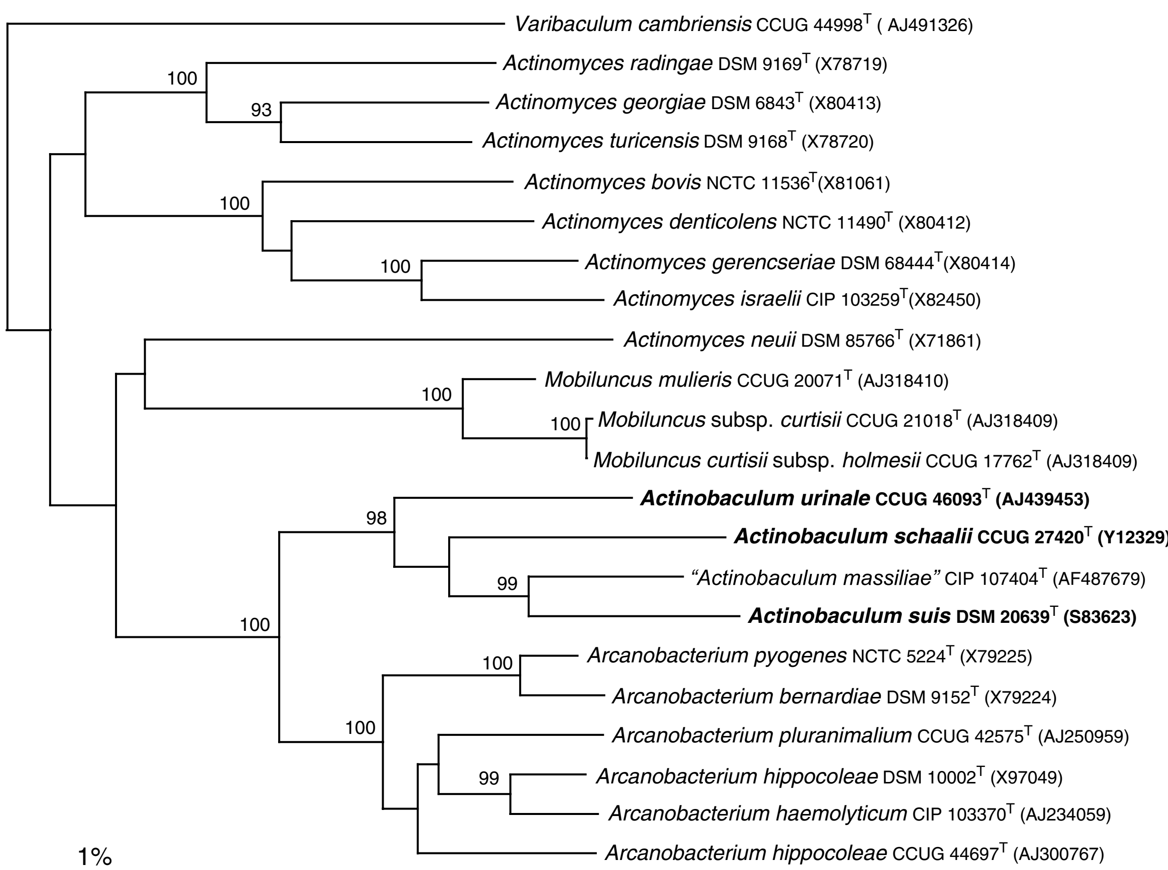

FIGURE 58. Unrooted neighbor-joining tree depicting the estimated phylogenetic relationships of members of the genus *Actinobaculum* and their close relatives. The numbers on the branches refer to bootstrap values, determined from 1000 replications. Only values above 90% are shown. Bar = 1% sequence divergence.

suis, *Actinobaculum schaalii*, and *Actinobaculum urinale* are recognized. *Actinobaculum suis*, the type species of the genus, is an established pathogen of pigs and has had a somewhat confused taxonomic and nomenclatural history, having been assigned to a variety of genera including *Actinomyces*, *Corynebacterium*, and *Eubacterium* (Wegienek and Reddy, 1982). This species designation was first introduced by Gasperini (1892), but in the eighth edition of the *Bergey's Manual of Determinative Bacteriology* (Slack, 1974) it was cited as a *nomen dubium* because this species designation had not been validly published. Grässer (1957) isolated bacteria named *Actinobaculum suis* from mastitic swine, but in this case while the name was validly published, the description was inadequate and cultures were not available. Hence, the species *Actinobaculum suis* was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980). More recently, Franke (1973) described actinomycetes isolated from the udder of swine which he called *Actinobaculum suis*. The morphological and biochemical characteristics of these isolates appeared to be somewhat different from those of Grasser's strains, but they seemed to fit well within the genus *Actinomyces* (Slack and Gerencser, 1975). At present, it is impossible to decide whether *Actinobaculum suis* Grasser and *Actinobaculum suis* Franke are identical.

In a taxonomic study of "*Corynebacterium suis*", Wegienek and Reddy (1982) found that "*Corynebacterium suis*" strain Soltys 50052 is anaerobic, has rhamnose and lysine as major cell components, and produces acetate, formate, and ethanol as major end products of carbohydrate metabolism. In contrast, representatives of the genus *Corynebacterium* are aerobic or facultatively anaerobic organisms characterized by cell walls containing arabinose and galactose as the major sugar components and *meso*-diaminopimelic acid as the major diamino acid. Furthermore, corynebacteria produce major amounts of acetate, propionate, and formate and variable amounts of other acids as products of carbohydrate metabolism (Reddy and Kao, 1978). Thus, Wegienek and Reddy (1982) concluded that this strain did not belong to the genus *Corynebacterium* and they proposed, despite differences in cell-wall composition and DNA base ratios, that the organism should be included in the genus *Eubacterium*. Their proposal was based on a rather limited number of characteristics such as anaerobiosis, morphology, as well as absence of lactate, propionate, and succinate among the end products of carbohydrate metabolism. Using comparative sequence analysis of the 16S rRNA gene, Ludwig et al. (1992) showed that *Eubacterium suis* was a relatively close relative (93.8% sequence similarity) of *Actinomyces pyogenes*. These two organisms have the same cell-wall composition (lysine is the diamino acid; rhamnose and traces of mannose are the cell-wall sugars), contain type *c* cytochromes, and have a similar DNA G+C content, 55 and 56–58 mol%, respectively (Schaal, 1986b; Schaal and Pulverer, 1981; Soltys and Spratling, 1957; Wegienek and Reddy, 1982). Since the type strain of "*Actinomyces suis*" Franke is extant, Ludwig et al. (1992) proposed that "*Eubacterium suis*" should be transferred to the genus *Actinomyces* as "*Actinomyces suis*".

Following a study of *Actinomyces*-like organisms from clinical materials, Lawson et al. (1997) proposed the genus *Actinobaculum* to accommodate these organisms. 16S rRNA gene sequencing showed that they were distinct from previously described *Actinomyces* and *Arcanobacterium* species. However, *Actinomyces suis* was demonstrated to be a close phylogenetic relative (94.2% sequence similarity) of the newly isolated clinical strains and presented similar phenotypic and biochemical characteristics. Therefore it was reclassified as *Actinobaculum suis* and as the type species of the genus. A third species of *Actinobaculum* was proposed by Hall et al. (2003b) to accommodate an organism isolated from human urine, and this taxon exhibited phylogenetic and biochemical characteristics consistent with its assignment to the genus *Actinobaculum*. In 2002, Greub and Raoult described an organism isolated from human urine, and based on phylogenetic and biochemical studies, they identified it as a member of the genus *Actinobaculum* and proposed the name "*Actinobaculum massiliae*". Subsequently this organism was validly published as *Actinobaculum massiliense* (Greub and Raoult, 2006).

Differentiation of the genus *Actinobaculum* from other genera

Actinobaculum can be distinguished readily from its closest phylogenetic relatives using a combination of morphological, biochemical, and chemotaxonomic criteria. Differential characteristics of the species of *Actinobaculum* are presented in Table 10.

Differentiation of species of the genus *Actinobaculum*

Differential characteristics of the species of *Actinobaculum* are presented in Table 11.

List of species of the genus *Actinobaculum*

1. **Actinobaculum suis** Wegienek and Reddy 1982; "*Corynebacterium suis*" Soltys and Spratling 1957; Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 902[VP]

su′is. L. gen. n. *suis* of a hog, of a pig.

Slender, nonmotile, pleomorphic rods (1–3 by 0.5 μm) are arranged singly, in pairs (cells often at an angle to each other or in palisades), or in small clusters. Gram-stain-positive, but rather easily decolorized, especially in old cultures. Non-acid-fast and nonsporulating; does not survive heating at 80°C for 10 min. Capsules are not observed by capsule staining; however, a fringelike outer coat external to the cell wall is seen in thin-section electron micrographs. Colonies on anaerobic blood agar plates are 0.5–3.0 mm in diameter after 48 h, white, circular, and granular and have entire to slightly irregular margins. Colonies often have slightly raised centers, which gives them a fried-egg appearance. After 1 week, colonies are 3–5 mm in diameter and flatter. Growth is barely discernible after incubation for 7 d under 6% CO_2 or air. Peptone-yeast extract-starch broth supports excellent growth. The optimal pH is 7–8; no growth occurs at pH 5.0 or less. Growth is optimal at 37°C and in the temperature range, 30–43°C; no growth occurs at 22–23°C. Anaerobic. Metabolism is strictly fermentative. Glycogen, maltose, and starch are fermented. Acetate, ethanol, and formate are the main products from maltose fermentation. Adonitol, amygdalin, arabinose, cellobiose, dulcitol, erythritol, esculin, fructose, galactose, glucose, glycerol, inositol, inulin, lactose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, lactate, pyruvate, and threonine are not fermented. Strongly urease-positive. Does not produce catalase, indole, acetylmethylcarbinol, hydrogen sulfide, lipase, or lecithinase; ammonia is not produced from peptone. Esculin and gelatin are not hydrolyzed. Meat and milk are not digested. Nitrates are not reduced. Major amounts of type *b* cytochrome and minor amounts of type *c* cytochrome are synthesized. The cell-wall sugars are mannose and rhamnose. The cell-wall murein type is type A5a (L-Lys–L-Ala–Lys– D-Glu). Originally isolated from cases of cystitis and pyelonephritis and cases of metritis in pregnant sows. Not isolated from healthy sows but frequently recovered from urine and semen of apparently healthy boars. Sows can be infected artificially by intrarenal injection of live organisms plus 5% saponin. No demonstrable exotoxin is produced.

DNA G+C content (mol%): 55–57 (T_m).

Type strain: Soltys 50052, ATCC 33144, CCUG 19206, CIP 105361, DSM 20639, LMG 18291.

Sequence accession no. (16S rRNA gene): S83623.

2. **Actinobaculum massiliense** Greub and Raoult 2006, 2025[VP] (Effective publication: Greub and Raoult 2002, 3941.)

mas.si.li.en′se L. neut. adj. *massiliense* of or pertaining to *Massilia*, the Latin name of Marselle, where the organism was isolated.

The organism forms straight to slightly curved rods, some of which exhibit branching. It has nonmotile, non-acid-fast, Gram-stain-positive (easily decolorized) cells. Colonies on

sheep blood agar are 1 mm in diameter after 72 h of incubation at 37°C in a 5% CO_2 atmosphere, and there is no hemolysis. It is facultatively aerobic. Esculin and gelatin are not hydrolyzed. Nitrate is not reduced to nitrite. Acid is produced from glucose, glycogen, maltose, ribose, and xylose. The cellular fatty acids are of the straight chain saturated and monounsaturated types, with $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, and $C_{18:1}$ ω9c predominating.

Source (type strain): the urine of an 81-year-old woman with cystitis. Habitat is not known.

DNA G+C content (mol%): not determined.

Type strain: CCUG 47753, CIP 107404, DSM 19118.

Sequence accession no. (16S rRNA gene): AF487679.

3. **Actinobaculum schaalii** Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 902[VP]

schaa′li.i. N.L. gen. masc. n. *schaalii* of Schaal, to honor Klaus P. Schaal, contemporary German microbiologist, for his contributions to actinomycete microbiology.

Cells are straight to slightly curved rods, some of which exhibit branching, Gram-stain-positive, non-acid-fast, nonmotile, and non-spore-forming. Nonhemolytic. A weak CAMP reaction occurs. Facultatively anaerobic and catalase-negative. Acetate and succinate are the major end products of glucose fermentation. Acid is produced from glucose, maltose, ribose, and D-xylose. Some strains produce acid from L-arabinose, mannose, starch, sucrose, and trehalose. Acid is not produced from D-arabitol, *N*-acetyl-β-glucosamine, cyclodextrin, glycogen, lactose, mannitol, melezitose, melibiose, methyl-β-D-glucopyranoside, pullulan, raffinose, sorbitol, and D-tagatose. Hippurate is hydrolyzed. Esculin, gelatin, and urea are not hydrolyzed. α-Glucosidase, alanine-phenylalanine-proline arylamidase, and pyroglutamic acid arylamidase are produced. Alkaline phosphatase, arginine dihydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, glycyl-tryptophan arylamidase, and β-mannosidase activities are not detected. Pyrazinamidase and pyrrolidonylarylamidase activities are shown by some strains. Nitrate is not reduced to nitrite. Acetoin is not produced. The cell-wall murein type is A5a (L-Lys–Lys–D-Glu). The major cellular fatty acids are hexadecanoic, octadecanoic, and *cis*-delta-9-octadecenoic acids. Strains have been isolated from human blood and urine. The habitat is unknown but is probably the genital or urinary tract.

Source: human blood (chronic pyelonephritis, 64-year-old male).

DNA G+C content (mol%): 55–57 (HPLC).

Type strain: CCUG 27420, CIP 105739, CCM 4738, DSM 15541, LMG 18293.

Sequence accession no. (16S rRNA gene): Y12329.

4. **Actinobaculum urinale** Hall, Collins, Hutson, Falsen, Inganäs and Duerden 2003b, 682[VP]

u.ri.na′le. L. neut. adj. *urinale* of or belonging to urine.

Cells are straight to slightly curved Gram-stain-positive rods. Branching is not observed. Cells are non-acid-fast and non-spore-forming. After 48 h of anaerobic incubation on fastidious anaerobe agar supplemented with 5% horse blood, colonies are <1 mm in diameter, convex, smooth, entire-edged, gray or white, and weakly β-hemolytic. Facultatively anaerobic and catalase-negative. Lactic acid is the major end product of glucose metabolism together with minor amounts of acetic acid. Using the commercially available API systems, acid is produced from glucose and ribose; acid production from maltose and sucrose is variable and dependent on the test system used. Acid is not formed from D-arabitol, L-arabinose, cyclodextrin, glycogen, lactose, mannitol, mannose, melibiose, melezitose, methyl-β-D-glucopyranoside, pullulan, raffinose, sorbitol, tagatose, trehalose, or D-xylose. Hippurate is hydrolyzed, but gelatin and esculin are not. Arginine arylamidase, β-glucuronidase, and proline arylamidase are produced and urease may or may not be detected. Alanine phenylalanine proline arylamidase, arginine dihydrolase, acid phosphatase, alkaline phosphatase, alanine arylamidase, arginine arylamidase, α-arabinosidase, chymotrypsin, trypsin, cysteine arylamidase, esterase C4, ester lipase C8, α-fucosidase, α-galactosidase, β-galactosidase, β-galactosidase-6-phosphate, α-glucosidase, β-glucosidase, glycyl tryptophan arylamidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, leucyl glycine arylamidase, lipase C14, α-mannosidase, β-mannosidase, *N*-acetyl-β-glucosaminidase, phosphoamidase, phenylalanine arylamidase, pyroglutamic acid arylamidase, pyrazinamidase, serine arylamidase, tyrosine arylamidase, and valine arylamidase are not detected. Acetoin is not produced. Indole-negative. Nitrate is not reduced to nitrite. The cellular fatty acids are of the straight chain saturated and monounsaturated types, with $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, and $C_{18:1}$ ω9*c* predominating.

Source (type strain): human urine. Habitat is not known.

DNA G+C content (mol%): not determined.

Type strain: R9242, CCUG 46093, CIP 107424, DSM 15805.

Sequence accession no. (16S rRNA gene): AJ439453.

Genus III. **Arcanobacterium** Collins, Jones and Schofield 1983, 438[VP] (Effective publication: Collins, Jones and Schofield 1982b, 1280.), emend. Lehnen, Busse, Frölich, Krasinska, Kämpfer and Speck 2006, 864[VP]

Atteyet F. Yassin and Klaus P. Schaal

Ar.ca.no.bac.te′ri.um. L. adj. *arcanus* secret, hidden, secretive; L. neut. n. *bacterium* a small rod; N. L. neut. n. *Arcanobacterium* secretive bacterium.

Slender, irregular, bacillary forms predominate during the first **18** h of growth; many cells are **arranged at an angle to give V-formations**. As growth proceeds cells become granular and segmented so that they resemble small and irregular cocci. Both rods and coccoid cells are Gram-stain-positive, non-acid fast and non-motile; endospores are not formed. **Facultatively anaerobic**; growth is considerably enhanced in an atmosphere of increased CO_2-tension. Growth is sparse on ordinary media

but enhanced by blood or serum. The optimum temperature for growth is **37°C**. Organisms will not withstand heating at **60°C** for **15 min**. **Chemoorganotrophic**, having a fermentative type of carbohydrate metabolism. Fermentation end products include acetic and lactic acids; the amount of succinic acid produced may vary from species to species and may even be difficult to detect. Catalase-negative. Nitrate reduction is usually negative. Characteristic **amino acids of the cell-wall peptidoglycan** of those species whose peptidoglycan has been examined in detail are based on L-lysine. Other chemotaxonomic properties include **rhamnose** as diagnostic whole-cell sugar, lack of mycolic acids and *N*-acetylated muramic acid residue of the **peptidoglycan**.

DNA G+C content (mol%): 50–63.8 (T_m, HPLC).

Type species: **Arcanobacterium haemolyticum** Collins, Jones and Schofield 1983, 438[VP] (Effective publication: Collins, Jones and Schofield 1982b, 1280).

Further descriptive information

Phylogeny. Current phylogenetic data indicate that members of the genus *Arcanobacterium* constitute a separate phylogenetic lineage within the *Actinomycetaceae* (Figure 19). It is evident from the tree that the genera *Arcanobacterium* and *Actinobaculum* have a close phylogenetic affinity. From a phylogenetic point of view, it appears that members of the genera *Arcanobacterium* and *Actinobaculum* have originated as descendants of a common ancestor. The phylogenetic coherence of the genus *Arcanobacterium* is supported by a set of distinct signature nucleotides (Table 1).

The intrageneric relationships based on comparisons of the almost complete 16S rRNA gene sequences of the nine *Arcanobacterium* species are shown in Figure 19 of the *Actinomyces* chapter. The type strains of the nine *Arcanobacterium* species form two 16S rRNA gene sequence subclusters in which the species of each subcluster show a high degree of interspecies relatedness. Bootstrap values of 100% indicate that these subclusters are of statistical significance. Subcluster 1 contains the type species of the genus, *Arcanobacterium haemolyticum*, as well as *Arcanobacterium phocae* and *Arcanobacterium pluranimalium*. The 16S rRNA gene sequence similarities within members of this subcluster range from 95.4 to 97.4%. Subcluster 2 contains the species *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi* and *Arcanobacterium pyogenes*. The 16S rRNA gene sequence similarities within the type strains of these species range from 95.3 to 98.6%. Members of subclusters 1 and 2 can be separated by 4.4–7.5% sequence divergence. In addition, members of the two subclusters can be clearly distinguished by a set of subcluster-specific nucleotides, which can be considered molecular signatures. The positions of these nucleotides in the 16S rRNA sequence are indicated in Table 12.

The branching point of the *Arcanobacterium hippocoleae* sequence was close to the bifurcation point of the two *Arcanobacterium* lineages. However, this species branched with members of subcluster 1 in the neighbor-joining (Saitou and Nei, 1987) and maximum likelihood (Felsenstein, 1981) trees. The finding that *Arcanobacterium hippocoleae* shows 1% more 16S rRNA gene sequence similarity to members of subcluster 1 than to members of subcluster 2 may be indicative of a specific relatedness to the former cluster as indicated in Figure 19 of the *Actinomyces* chapter. This relationship is also expressed by the presence of six signature nucleotides that are shared between *Arcanobacterium hippocoleae* and members of subcluster 1, while five signatures are common to members of subcluster 2. Bootstrap values of the branching points (98% significance for subcluster 1 members) indicate that members of subcluster 1 are the closest phylogenetic neighbors of *Arcanobacterium hippocoleae*.

Cell morphology. The cellular morphology of the genus *Arcanobacterium* as described by Collins et al. (1982b) for bacteria formerly named "*Corynebacterium haemolyticum*" is as follows: "On blood agar plates, slender, irregular, bacillary forms predominate during the first 18 h; many cells are arranged at an angle to give V-formations. As growth proceeds, organisms become granular and segmented so that they resemble small and irregular cocci. Both rods and coccoid cells are Gram-stain-positive, non-acid fast and non-motile; endospores are not formed".

The morphology of *Arcanobacterium pyogenes* by and large conforms to this description (Reddy et al., 1982; Schaal, 1969). The same is true for *Arcanobacterium abortisuis*, *Arcanobacterium phocae* and *Arcanobacterium bernardiae*, whereas *Arcanobacterium hippocoleae* and *Arcanobacterium pluranimalium* appear to be less coccoid. The cells of *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* are short pleomorphic rods.

Surface colonies of *Arcanobacterium haemolyticum* on blood agar were described to be small after 24 h of incubation at 36±1°C, becoming larger upon extended incubation (Collins and Cummins, 1986a). They are circular, discoid, slightly raised, opaque and nonpigmented with a butyrous consistency, and they show β-hemolysis. Colonies of *Arcanobacterium pyogenes* are very similar, while *Arcanobacterium bernardiae* varies concerning β-hemolysis. *Arcanobacterium phocae* also produces a potent hemolysin, whereas *Arcanobacterium hippocoleae* is weakly β-hemolytic, and *Arcanobacterium pluranimalium* was reported to be α-hemolytic.

After 48 h of growth under aerobic conditions on sheep blood agar, colonies of *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* are translucent, convex, approximately 0.5 mm in diameter and surrounded by a narrow zone of β-hemolysis. Colonies of *Arcanobacterium abortisuis* have a translucent smooth surface with a diameter of about 2 mm on TMVL agar (Azuma et al., 2009).

Cell-wall composition. The species currently included in the genus *Arcanobacterium* display considerable chemotaxonomic heterogeneity in particular with regard to their menaquinone, polar lipid and cellular fatty acid composition (Table 13).

[b]Data for *Arcanobacterium haemolyticum* from Lawson et al. (1997); data for *Arcanobacterium phocae* from Schaal et al. (2006); data for *Arcanobacterium pluranimalium* from Lawson et al. (2001a); data for *Arcanobacterium bernardiae* from Funke et al. (1995); data for *Arcanobacterium pyogenes* from Pascual Ramos et al. (1997b).

[c]A.F. Yassin (unpublished).

[d]Data from Cummins and Harris (1956).

Menaquinone composition. The principal respiratory quinones among the *Arcanobacterium* species are menaquinones with eight, nine, ten and eleven isoprene units. Two different menaquinone patterns could be distinguished within the *Arcanobacterium* species (Table 13). *Arcanobacterium bernardiae* possesses a tetrahydrogenated menaquinone with ten isoprene units [MK-10(H_4)] as the major component and small amounts of tetrahydrogenated menaquinones with nine [MK-9(H_4)] and eleven [MK-11(H_4)] isoprene units. A similar pattern was also found in *Arcanobacterium abortisuis*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi* and *Arcanobacterium pyogenes*. In contrast, tetrahydrogenated menaquinones with nine isoprene units [MK-9(H_4)] appear to be the major components present in *Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pluranimalium* with trace amounts of MK-8(H_4). The menaquinone structure of *Arcanobacterium hippocoleae* has not been reported.

Polar lipids. The reports on the distribution of polar lipids among the *Arcanobacterium* species are controversial. Schaal et al. (2006) reported a type PIII phospholipid pattern (Lechevalier et al., 1977) with phosphatidylcholine as key diagnostic phospholipid in *Arcanobacterium bernardiae*, *Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pyogenes*. Lehnen et al. (2006) reported the presence of diphosphatidylglycerol, phosphatidylglycerol, three unknown phosphoglycolipids (PGL), an unknown aminolipid (AL2), two unknown phospholipids and an unknown aminophospholipid as predominant compounds in *Arcanobacterium bonasi* and *Arcanobacterium bialowiezense*. The two species could be distinguished by the presence of hydrophilic lipids in *Arcanobacterium bialowiezense*; an unknown aminoglycolipid and an unknown aminophosphoglycolipid. Similar, but not identical, profiles were detected for *Arcanobacterium pyogenes* DSM 20630[T] and *Arcanobacterium haemolyticum* DSM 20595[T] (Lehnen et al., 2006). On the other hand, Azuma et al. (2009) reported that the phospholipid pattern of *Arcanobacterium abortisuis* belongs to phospholipid type PII (Lechevalier et al., 1977). This pattern contained basically phosphatidylethanolamine as characteristic phospholipid, in addition to two unknown phosphatidylinositol mannosides.

Recent investigations (A. F. Yassin, unpublished) of the phospholipid pattern from *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pyogenes* indicated that the phospholipids composition of these species were basically similar to the phospholipid pattern detected in *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* as reported by Lehnen et al. (2006). These five species contained diphosphatidylglycerol (DPG), phosphatidylglycerol (PG) and phosphatidylinositol (PI), in addition to a number of unknown phospholipids. In contrast to *Arcanobacterium haemolyticum* and *Arcanobacterium phocae*, a phosphoglycolipid with unknown composition was detected in *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, and *Arcanobacterium pyogenes*. Similar phosphoglycolipid was detected in *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* (Lehnen et al., 2006). No nitrogen-containing phospholipids, i.e. phosphatidyl ethanolamine or phosphatidyl choline, were detected in the phospholipid extracts of these species. Thus, the phospholipid patterns of *Arcanobacterium abortisuis, Arcanobacterium bernardiae, Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pyogenes* belonged to phospholipid type PI according to Lechevalier et al. (1977). Apart from the unkown aminolipids, aminophospholipids and aminophosphoglycolipids detected in *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* (as determined by Lehnen et al., 2006), the phospholipid pattern of the latter two species should belong to phospholipid type PI.

Fatty acid composition. Earlier reports (Collins et al., 1982a; Lechevalier, 1977) and recent investigations (A.F. Yassin, unpublished) on cellular fatty acid of members of the genus *Arcanobacterium* showed that the fatty acid profiles composed of predominantly straight-chain saturated and monounsaturated acids. The major monounsaturated fatty acid was of the oleic acid series ($C_{18:1}$ ω9*c*). Small amounts of *cis*-vaccenic acid ($C_{18:1}$ ω7*c*) and *trans*-vaccenic acid ($C_{18:1}$ ω7*t*) were variably distributed in members of the genus *Arcanobacterium*. Furthermore, substantial amounts of octadecadienoate ($C_{18:2}$ ω6,9*c*) was regularly distributed in all the type strains of the validly published *Arcanobacterium* species. Moreover, trace amounts of methyl-branched-chain fatty acids (anteiso-, iso-) were detected in all *Arcanobacterium*. The reports on the distribution of cyclopropanoic acids among the *Arcanobacterium* species are controversial. Collins et al. (1982b) reported the presence of *cis*-9,10-methylenehexadecanoic acid (17Δ7*c*) and lactobacillic acid (*cis*-11,12 methylene-octadecanoic acid; 19Δ7*c*) in one strain of *Arcanobacterium haemolyticum* (strain NCTC 9697). However, Lehnen et al. (2006) and Azuma et al. (2009) did not report the presence of 17Δ7*c* or 19Δ7*c* in the cellular fatty acid profiles of the type strains of *Arcanobacterium abortisuis*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi*, *Arcanobacterium haemolyticum* and *Arcanobacterium pyogenes*. The presence of cyclopropanoic acids in members of the genus *Arcanobacterium* as well as the presence of the tetraenoic acid ($C_{20:4}$ ω6,9,12,15*c*) reported in *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi* and *Arcanobacterium haemolyticum* by Lehnen et al. (2006) are not verified by gas-chromatography-mass-spectrometric analysis (GC-MS) of the fatty acid methyl esters of the type strains of validly published *Arcanobacterium* species (A.F. Yassin, unpublished).

Peptidoglycan composition. The mode of cross-linkage and the amino acid composition of the tetrapeptide bridge of the peptidoglycan layer of several *Arcanobacterium* species have been published previously (Collins et al., 1982a; Lawson et al., 2001a; Pascual Ramos et al., 1997b; Schaal et al., 2006). This corresponds to peptidoglycan type A5 according to the nomenclature of Schleifer and Seidl (1985). Thus, *Arcanobacterium haemolyticum*, *Arcanobacterium phocae* and *Arcanobacterium pluranimalium* exhibit subtype A5α (L-Lys–L-Lys–D-Glu), while *Arcanobacterium bernardiae* and *Arcanobacterium pyogenes* possess subtype A5α (L-Lys–L-Ala–L-Lys–D-Glu). The cell-wall peptidoglycan of *Arcanobacterium abortisuis* contains glutamic acid, alanine and lysine in the molar ratio of 1:2:1 (Azuma et al., 2009). Although almost one half of the validly published species of the genus *Arcanobacterium* have not yet been analyzed with respect to peptidoglycan composition, the distribution of peptidoglycan types matches by and large the phylogenetic clustering of members of the genus *Arcanobacterium*. The muramic acid residue of the glycan moiety of the cell-wall peptidoglycan, as far as examined for members of the genus *Arcanobacterium*, is *N*-acetylated. Analysis of whole-cell hydrolysates from *Arcanobacterium*

species reveals the regular presence of rhamnose and glucose as diagnostic cell-wall sugar.

Metabolism and metabolic pathways. Arcanobacteria are facultatively anaerobic having a fermentative type of carbohydrate metabolism. Fermentation end products are acetic and lactic acids; the amount of succinic acid produced may vary from species to species and may even be difficult to detect.

The catalase production is negative in *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi*, *Arcanobacterium hippocoleae* and *Arcanobacterium pyogenes*; it is positive in *Arcanobacterium pluranimalium* and variable in *Arcanobacterium phocae*. Catalase activity in *Arcanobacterium haemolyticum* is usually negative, but some strains may show weak catalase production.

Acid production from various carbohydrates, enzyme activities of *Arcanobacterium* species, and several other physiologic properties are summarized in Table 14. Nearly all members of the genus ferment glucose and maltose, and none produce urease or hydrolyze esculin. All of the other physiological characters vary among the *Arcanobacterium* species and may therefore be used for differentiating or identifying them (Table 14).

Pathogenicity. Arcanobacteria are known as opportunistic pathogens of human and a number of important livestock species, and usually infect from an endogenous, commensal source (Baumann et al., 2001; Dieleman et al., 1989; Jonsson et al., 1991; Jost and Billington, 2005; Lechtenberg et al., 1988; Therriault et al., 2008; Volante et al., 2008). Infections can be transmitted from animal to animal, from animals to humans, or even between humans. However, members of different species vary considerably with regard to virulence, types of pathological lesions induced and host specificity.

Human infections. Man is the main reservoir of *Arcanobacterium haemolyticum*. The clinical symptoms of *Arcanobacterium haemolyticum* infections are similar, this organism being predominantly isolated from pharyngeal infections, skin lesions and septicemia (Carlson et al., 1994b; Collins and Cummins, 1986a; Dethy et al., 1986; Gaston and Zurowski, 1996; Jurankova and Votava, 2001; Moreno Montesinos et al., 1989; White and Foshee, 2000) with and without metastatic abscess formation (Dieleman et al., 1989). Primary deep-seated abscesses (Barnham and Bradwell, 1992), cellulitis including a fulminant tubo-ovarian soft tissue infection (in coculture with fusobacteria; Batisse-Milton et al., 1995) and an orbital cellulitis (Ford et al., 1995), surgical wound infections, an infected foot wound, or endocarditis due to this organism have also been reported (Alos et al., 1995; Dobinsky et al., 1999; Esteban et al., 1994; Ritter et al., 1993; Skov et al., 1998). *Arcanobacterium haemolyticum* was identified in blood culture of a woman with developed symptoms of pharyngitis with necrotising pneumonia (van der Eerden et al., 2006) and from multiple peritonsillar abscesses in a young male with a four-week history of sore throat (Bomke et al., 2009). A case of severe sepsis caused by *Arcanobacterium haemolyticum* in male with a medical history significant for mild asthma has been reported by Therriault et al. (2008). However, on the whole this organism has been rarely documented in systemic infections (Dobinsky et al., 1999; Minarik et al., 1997; Parija et al., 2005) and even less in brain abscesses (Chhang et al., 1991; Vargas et al., 2006).

Human infections with *Arcanobacterium pyogenes* are uncommon and the microorganism has hitherto primarily been considered a zoonotic pathogen (Smith, 1966; Sørensen, 1974). Human infections are usually presented as acute pharyngitis, urethritis or as cutaneous or subcutaneous suppurative processes (Barksdale et al., 1957; Collins and Jones, 1982; Gahrn-Hansen and Frederiksen, 1992; Reddy et al., 1982), but bacteremia has also been reported (Barnham, 1988). Additional *Arcanobacterium pyogenes* infections include septic arthritis in a diabetic farmer (Lynch et al., 1998) and endemic leg ulcers in Thailand (Kotrajaras and Tagami, 1987).

Arcanobacterium bernardiae has been isolated from various clinical sources including blood, abscesses, and eye infections (Funke et al., 1995). More recently, urinary tract infections, septic arthritis and an unusual case of prosthetic joint infection due to this organism were also described (Adderson et al., 1998; Lepargneur et al., 1998; Loïez et al., 2009). The remaining *Arcanobacterium* species appear to occur only in animals.

Animal infections. *Arcanobacterium pyogenes* is a ubiquitous inhabitant of the mucous membranes of cattle, swine, and many other animal species (Jost and Billington, 2005). As an opportunistic pathogen, *Arcanobacterium pyogenes* can cause a variety of suppurative diseases in animals compromised by previous microbial infection or trauma. Economically significant disease includes mastitis in cows, often associated with *Peptoniphilus* (*Peptostreptococcus*) *indolicus*, and peritonitis and pleuritis in swine (Glage, 1903; Reddy et al., 1982; Roberts, 1968). *Arcanobacterium pyogenes* was also found to be etiologically involved in pneumonia in calves (Vogel et al., 2001), hematogenous osteomyelitis in cattle (Firth et al., 1987), purulent osteomyelitis in fattening pigs (Bürgi et al., 2001), a pyothorax in a one-month-old female kitten (Gulbahar and Gurturk, 2002), chronic otitis externa in a cat and urinary tract infection in a dog (Billington et al., 2002), hypertrophic osteopathy in a dog, the retention of fetal membranes in ewes (Tzora et al., 2002), facial and mandibular abscesses in blue duiker, often associated with *Fusobacterium necrophorum* (Roeder et al., 1989), intracranial abscesses in white-tailed deer (Baumann et al., 2001) and a steer (Strain et al., 1987), and in lymphadenitis in camels (Moustafa, 1994). The development of renal medullary amyloidosis in Dorcas gazelles also appeared to be related to chronic or recurring *Arcanobacterium pyogenes* infections (Rideout et al., 1989).

Experimental mastitis induced by intramammary challenge with *Arcanobacterium pyogenes* was found to be more severe in dry than in lactating glands and was very difficult to eliminate in the dry period even by antibiotic treatment, whereas lactating glands recovered more easily either spontaneously or after administration of antibiotics. Combined infections of *Arcanobacterium pyogenes* with *Peptoniphilus indolicus* took an especially severe clinical course and showed a higher frequency of systemic involvement (Hillerton and Bramley, 1989).

Arcanobacterium haemolyticum has been known as an occasional cause of infections in farm animals (Collins and Jones, 1982). Recently, the organism was identified as one of the pathogens responsible for mandibular and maxillary abscesses in pet rabbits (Tyrrell et al., 2002).

Of the remaining *Arcanobacterium* species, *Arcanobacterium bernardiae* has as yet only been isolated from human sources. *Arcanobacterium phocae* has been recovered in mixed culture from various tissues and fluids of common seals (*Phoca vitu-*

[b]Data compiled from Collins et al. (1982b); Funke et al. (1995); Pascual Ramos et al. (1997b); Lawson et al. (2001a); Hoyles et al. (2002b); Lehnen et al. (2006); Azuma et al. (2009); A. F. Yassin (unpublished).

[c]All strains are negative for acid production from L-arabinose, raffinose, L-rhamnose, salicin, D-sorbitol and sucrose as well as arginine dihydrolase, β-glucosidase, nitrate reductase and urease activity.

lina) and gray seals (*Halichoerus grypus*), but its pathological significance was unclear (Pascual Ramos et al., 1997b). Johnson et al. (2003) reported on the isolation of *Arcanobacterium phocae* in animals from the Pacific Ocean. The overall prevalence of *Arcanobacterium phocae* among cultured stranded marine mammals was 8%. *Arcanobacterium hippocoleae* was cultured from a female Arab horse with vaginal discharge (Hoyles et al., 2002b) and isolated from a case of necrosuppurative placentitis and stillbirth in an American Quarterhorse mare (Bemis et al., 2008). *Arcanobacterium pluranimalium* has been isolated from the spleen of a dead harbor porpoise and a lung abscess of a dead sallow deer (Lawson et al., 2001a), whereas *Arcanobacterium abortisuis* has been isolated from a sow's placenta after an abortion (Azuma et al., 2009). *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi* were isolated from the prepuce of European bison (*Bison bonasus*) bulls suffering from balanoposthitis (Lehnen et al., 2006).

Antigenic structure. *Arcanobacterium haemolyticum* infection induces an antibody response in the host. This was demonstrated in sera of patients with acute infection or from convalescents (Nyman et al., 1997). These antibodies react primarily with four distinct cell-wall-associated proteins with estimated molecular masses of 80, 60, 50, and 30 kDa.

Arcanobacterium haemolyticum has been reported to produce phospholipase D (PLD), an extracellular toxin with antigenic properties (Cuevas and Songer, 1993; McNamara et al., 1995; Skalka et al., 1998; Votava et al., 2001). Neutralizing antibodies against PLD of *Arcanobacterium haemolyticum* have been detected in patients with tonsillitis (Votava et al., 2001). Skalka et al. (1998) used PLD neutralization to examine sera of humans with a spontaneous infection by *Arcanobacterium haemolyticum*. They found that the titres of sera neutralizing the homologous PLD were always significantly higher than those neutralizing the heterologous PLD. The antigenic properties of PLD from *Arcanobacterium haemolyticum* (PL D-A) and from *Corynebacterium pseudotuberculosis* (PL D-C) were similar but not identical (Skalka et al., 1998).

Arcanobacterium pyogenes secret pyolysin (PLO), a cholesterol-dependent cytolysin, an important host-protective antigen (Billington et al., 1997). However, this molecule is toxic and its usefulness as a vaccine without prior inactivation is limited. Three genetically toxoided, nonhemolytic PLO molecules, HIS-PLO.F_{497}, HIS-PLO.P_{499}, and HIS-PLO.A_{522}, were found to be nontoxic, and vaccinated mice were protected from infection, indicating the potential of these toxoids as vaccines (Jost et al., 2003).

Antigens of the other *Arcanobacterium* species have not been studied.

Virulence factors. *Arcanobacterium pyogenes* expresses several known virulence factors that may contribute to its pathogenicity. These include pyolysin, which is a hemolysin with cytolytic activity for immune cells; two neuraminidases (NanH and NanP) required for adhesion to epithelial cells (Billington et al., 1997; Jost et al., 1999, 2001, 2002); a collagen-binding protein (CbpA) required for adhesion to collagen rich tissues (Pietrocola et al., 2007); and fimbriae (similar to type 2 fimbriae of *Actinomyces naeslundii*) that might be involved in host adhesion (Jost and Billington, 2005).

Arcanobacterium haemolyticum produces phospholipase D as one of its soluble toxins (Cuevas and Songer, 1993). This toxin is a protein of approximately 31.5 kDa and is related to, but not identical with, the phospholipases D of *Corynebacterium pseudotuberculosis* and *Corynebacterium ulcerans*. Virulence factors of the other *Arcanobacterium* species have not been studied.

Susceptibility to antibiotics. *Arcanobacterium haemolyticum* is susceptible to most classes of antimicrobial drugs, including carbapenems, cephalosporins, clindamycin, macrolides, penicillins, tetracyclines, and vancomycin (Almuzara et al., 2002; Arikan et al., 1997; Carlson et al., 1994a, 1999). General resistance has been reported against trimethoprim/sulfamethoxazole (Therriault et al., 2008). While treatment options are numerous, Therriault et al. (2008) recommend the use of intravenous penicillin or a cephalosporin as first-line pharmacologic management of deep-seated infections caused by this organism, whereas Van der Eerden et al. (2006) found that a macrolide antibiotic was the treatment of choice for a case of pharyngitis caused by *Arcanobacterium haemolyticum*.

Although *Arcanobacterium haemolyticum* is susceptible (thus far, universally) to penicillin by *in vitro* MIC testing, treatment failures have been documented (Bomke et al., 2009; Nyman et al., 1990; Osterlund, 1995; Volante et al., 2008). Clinical failures that have been reported could be associated with penicillin tolerance (Carlson et al., 1999). Isolates resistant to ciprofloxacin (Vargas et al., 2006), vancomycin (French et al., 1992), macrolides and quinolones (Carlson et al., 1999) have also been reported.

Arcanobacterium pyogenes is susceptible to third generation cephalosporins (Sheldon et al., 2004). Penicillin was reported to be highly effective against *Arcanobacterium pyogenes* (Ali, 2000; Guerin-Faublee et al., 1993). On the other hand, antimicrobial susceptibility of *Arcanobacterium pyogenes* strains isolated from cattle showed that some isolates were resistant to tetracyclines, macrolides, and sulfonamides (Trinh et al., 2002; Werckenthin et al., 2007). All 18 isolates of *Arcanobacterium phocae* recovered from marine mammals were 100% susceptible to amikacin, ampicillin, amoxicillin/clavulanate, cefazolin, ceftiofur, ceftizoxime, chloramphenicol, enrofloxacin, erythromycin, gentamicin, oxacillin, penicillin, rifampin, tetracycline, ticarcillin/clavulanate, trimethoprim-sulphamethoxazole (Johnson et al., 2003). This suggests that beta-lactam antibiotics should be useful in treating *Arcanobacterium phocae* infections in marine mammals. Detailed studies on the antibiotic susceptibility of the remaining *Arcanobacterium* species have not been reported.

Habitat and ecology. Information on the natural habitat of arcanobacteria is scarce, although it has been assumed that these organisms occur as commensals of the mucous membranes of domestic animals such as cattle, sheep, swine, and goats (Billington et al., 2002; Carter and Chengappa, 1991; Reddy et al., 1982). In a study on the Gram-positive tonsillar and nasal flora of piglets, Baele et al. (2001) found that *Arcanobacterium pyogenes* was one of the common colonizers of the tonsils of pigs before and after weaning but not of the nasal conchae. In addition, this organism has been isolated from semen of beef breed bulls (Sprecher et al., 1999) without a significant relationship between the cultural results and possible sperm abnormalities. This is in accordance with the findings of Olson et al. (2002). *Arcanobacterium pyogenes*, as certain *Actinomyces* species, is able to produce biofilms experimentally.

Another interesting finding is that *Arcanobacterium haemolyticum* could be identified as one of the major secondary colonizers of leprosy skin ulcers (Sturm et al., 1996) and may contribute to the inflammatory reaction of these lesions. The vast majority of *Arcanobacterium* isolates originated, however, from various pathological conditions that were thought to be etiologically related to these microbes and that has been discussed in the section on Pathogenicity.

Isolation, enrichment and maintenance procedures

For primary isolation and maintenance, complex media such as Columbia blood agar supplemented with 5% horse, sheep or human blood, BHI broth (or agar) or trypticase soy broth (or agar) have been recommended and are usually satisfactory. Good growth is obtained for *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, and *Arcanobacterium bonasi* in BHI broth incubated at 37°C under aerobic conditions. Best growth of *Arcanobacterium bialowiezense* occurred on BHI agar supplemented with 1% Tween 80 at 37°C. *Arcanobacterium haemolyticum* and *Arcanobacterium hippocoleae* are more difficult to grow in liquid media. However, addition of serum may enhance growth of *Arcanobacterium haemolyticum* considerably. Thus, a suitable liquid medium for *Arcanobacterium haemolyticum* consists of brain heart infusion broth supplemented with 5% horse serum (Collins and Jones, 1982). All of the other *Arcanobacterium* species apparently grow well on Columbia blood agar supplemented with 5% horse or sheep blood and incubated under increased CO_2 tension (~5%) at 36±1°C.

Recognition of *Arcanobacterium haemolyticum* in cultures from clinical specimens is often hampered by its delayed β-hemolysis and the presence of additional pathogens (e.g., streptococci) or microbes from the indigenous flora of the affected mucous membranes. Thus, media for selective isolation or improved recognition of this organism were developed: Coman et al. (1996) used a medium containing 5% sheep blood agar and 3.5% NaCl for selective isolation of *Arcanobacterium haemolyticum* from pharyngeal swabs of children. Jurankova and Votava (2001) applied sheep blood agar with a streak of *Staphylococcus aureus* to recognize *Arcanobacterium haemolyticum* on the basis of the reverse CAMP (Christie, Atkins and Munch-Petersen) phenomenon. The medium of Votava et al. (2000) containing Columbia blood agar base and 5% washed sheep erythrocytes sensitized with equi factor (EF) of *Rhodococcus equi* is based upon the same principle.

Cultures in routine use may be maintained by weekly transfer on Columbia blood agar supplemented with 5% sheep blood and incubated under increased CO_2 tension (~5%) at 36±1°C. For longer preservation (1–10 years or longer) freezing or lyophilization is recommended.

Differentiation of the genus *Arcanobacterium* from other genera

Arcanobacterium species resemble a variety of other Gram-stain-positive, diphtheroidal or coccobacillary genera morphologically and/or physiologically. However, comparative chemotaxonomic studies of cell-wall components allowed well differentiation between members of the arcanobacteria from *Actinomyces bovis* (as representative of the genus *Actinomyces sensu stricto), Actinobaculum*, and *Mobiluncus* (Table 15). Thus, the salient chemotaxonomic features of the type strains of *Arcanobacterium haemolyticum*, the type species of the genus, include cell-wall chemotype V (Lechevalier and Lechevalier, 1970) with the peptidoglycan subtype A5α (L-Lys–L-Lys–D-Glu), rhamnose as diagnostic whole-cell sugar; tetrahydrogenated menaquinones with eight [MK-8(H_4)] and nine [MK-9(H_4)] isoprene units, the predominant menaquinone being MK-9(H_4); the long-chain fatty acids are straight-chain saturated, monounsaturated as well as branched chain fatty acids of the iso- and anteiso-types; a muramic acid residue of the peptidoglycan that is N-acetylated, and DNA G+C contents between 50 and 58 mol%.

Taxonomic comments

The genus *Arcanobacterium* was described by Collins et al. (1982b) to accommodate bacterial strains originally isolated from infected American soldiers and previously named "*Corynebacterium haemolyticum*" (MacLean et al., 1946). However, the species exhibits little similarity to typical corynebacteria and its placement in the genus *Corynebacterium* was questioned by several workers (Barksdale, 1970; Barksdale et al., 1957; Collins et al., 1982a; Cummins and Harris, 1956; Jones, 1975; Minnikin et al., 1978; Schofield and Schaal, 1981). Furthermore, the relationship of "*Corynebacterium haemolyticum*" to the species "*Corynebacterium pyogenes*" (Glage) remained unclear. In a study of cell-wall compositions in some Gram-stain-positive bacteria, Cummins and Harris (1956) noted that the cell-wall compositions of "*Corynebacterium pyogenes*" and "*Corynebacterium haemolyticum*" were obviously similar to one another but differed both in sugar and amino acid composition from the other corynebacteria (i.e., neither species contains arabinose or galactose, lysine is the diamino acid of the peptidoglycan, and A_2pm is absent). On the other hand, Cummins and Harris (1956) found that rhamnose was present in both organisms, and this, together with the fact that alanine, glutamic acid and lysine were the major amino acid components, led these authors to suggest that the two organisms were related to the streptococci. This view was upheld by Barksdale et al. (1957) who suggested not only that "*Corynebacterium haemolyticum*" and "*Corynebacterium pyogenes*" should be reclassified in the genus *Streptococcus*, but also that "*Corynebacterium haemolyticum*" was a mutant form of "*Corynebacterium pyogenes.*"

In the 8th edition of *Bergey's Manual of Determinative Bacteriology*, both taxa were listed in an addendum to the genus *Corynebacterium* (Cummins et al., 1974), and "*Corynebacterium haemolyticum*" does not appear in the Approved Lists of Bacterial Names (Skerman et al., 1980). Later, numerical phenetic (Schofield and Schaal, 1981) and chemical (Collins et al., 1982a) studies showed that "*Corynebacterium haemolyticum*" and "*Corynebacterium pyogenes*" are two distinct taxa. The discovery of tetrahydrogenated menaquinones in "*Corynebacterium pyogenes*" and "*Corynebacterium haemolyticum*" (Collins et al., 1982a) was not in accord with the inclusion of these taxa in the genus *Streptococcus*. The majority of streptococci completely lack respiratory quinones, although some unsaturated naphthoquinones have been detected in a few group D and group N streptococci (Collins and Jones, 1979b; Collins and Jones, 1979a). In addition, fatty acid data (Collins et al., 1982a) did not support the view of Barksdale et al. (1957) that "*Corynebacterium haemolyticum*" should be reclassified in the genus *Streptococcus*. "*Corynebacterium haemolyticum*" possesses major amounts of monounsaturated fatty acids of the oleic acid series (synthesized via an aerobic pathway; Collins et al., 1982a). In contrast, members of the genus *Streptococcus* possess monounsaturated fatty acids of the *cis*-vaccenic acid series (synthesized via an anaerobic pathway; Kroppenstedt and Kutzner, 1978). Furthermore, the menaquinone patterns of "*Corynebacterium pyogenes*" and "*Corynebacterium haemolyticum*" were also incompatible with the retention of these species in the genus *Corynebacterium*. True corynebacteria generally possess dihydrogenated menaquinones with eight and nine isoprene units (Collins et al., 1977; Yamada et al., 1976). Tetrahydrogenated menaquinones with ten and nine isoprene units have, however, been reported in the genera *Actinomyces* (Collins et al., 1977) and *Propionibacterium* (Schwartz, 1973; Sone, 1974), respectively. Therefore, Reddy et al. (1982) as well as Collins and Jones (1982) proposed that "*Corynebacterium pyogenes*" should be reclassified in the genus *Actinomyces*, as "*Actinomyces pyogenes*". The presence of a peptidoglycan based upon L-lysine in "*Corynebacterium pyogenes*" supported this view since this amino acid is present in the peptidoglycan of *Arcanobacterium bovis* (Schleifer and Kandler, 1972). "*Corynebacterium pyogenes*" is physiologically similar to *Arcanobacterium bovis*, although it differs from *Arcanobacterium bovis* in being actively proteolytic (Cummins et al., 1974; Slack and Gerencser, 1975). However, the DNA base ratio of "*Corynebacterium pyogenes*" (58 mol% G+C) was not incompatible with its inclusion in the genus of *Arcanobacterium bovis*, which has 63 mol% G+C (Johnson and Cummins, 1972).

The taxonomic position of "*Corynebacterium haemolyticum*" remained equivocal. The results of lipid analyses did not support the view of Barksdale et al. (1957) that "*Corynebacterium haemolyticum*" is a mutant of "*Corynebacterium pyogenes.*" Phenotypically, "*Corynebacterium haemolyticum*" is very similar to *Arcanobacterium bovis* and also contains lysine in the cell-wall peptidoglycan. The menaquinone composition of "*Corynebacterium haemolyticum*" is distinct from that of *Arcanobacterium bovis* (Collins et al., 1977), and resembles that of the propionibacteria (Schwartz, 1973; Sone, 1974), but the results of cell wall and fatty acid analyses do not support this latter relationship. On the basis of cell-wall and lipid composition, the taxon "*Corynebacterium haemolyticum*" appeared quite distinct from all other coryneform and actinomycete taxa, thus warranting a new genus (Collins et al., 1982a). Therefore, on the basis of phenetic, peptidoglycan, fatty acid, menaquinone and DNA data (Collins et al., 1982a; Schleifer and Kandler, 1972; Schofield and Schaal, 1981), this taxon was reclassified by Collins et al. (1982b) in the new genus *Arcanobacterium* as *Arcanobacterium haemolyticum*.

The genus *Arcanobacterium* currently comprises nine validly published species, namely *Aracanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi*, *Arcanobacterium haemolyticum*, *Arcanobacterium hippocoleae*, *Arcanobacterium phocae*, *Arcanobacterium pluranimalium*, and *Arcanobacterium pyogenes*. Arriving at this current taxonomy has involved the inclusion of species transferred from other genera. For example, *Arcanobacterium pyogenes* was created by Pascual et al. (1997c) for the invalid "*Actinomyces pyogenes*" which was in turn created from the invalid "*Corynebacterium pyogenes*" by Reddy et al. (1982) and *Arcanobacterium bernardiae* was created from the invalid "*Actinomyces bernardiae*" (Pascual Ramos et al., 1997b). The chemotaxonomic features, as described previously (Collins et al., 1982b), include a cell-wall peptidoglycan based on lysine as the dibasic amino acid, rhamnose as the diagnostic cell-wall sugars, tetrahydrogenated menaquinone with nine isoprene units MK-9(H_4) as the major respiratory quinone, the long-chain fatty acids are straight-chain saturated and monounsaturated (oleic acid series) acids, lack of mycolic acids, and the DNA base composition was 50–52 mol% G+C.

In 1982, Collins and Jones found that tetrahydrogenated menaquinones with ten isoprene units MK-10(H_4) is the principal isoprenoid quinone of "*Actinomyces pyogenes*". This result is supported by recent analysis of menaquinone of this species (Lehnen et al., 2006). Furthermore, Lehnen et al. (2006) found that MK-10(H_4) is the principal isoprenoid quinone in *Arcanobacterium bialowiezense* and *Arcanobacterium bonasi*. This

incompatible menaquinone pattern with that of *Corynebacterium haemolyticum* [MK-9(H_4)], the type species of the genus, in addition to phylogeny points out toward a possible subdivision within the genus *Arcanobacterium* (Lehnen et al., 2006).

Similarity values of 16S rRNA gene sequence analyses for members of the genus range from 92.5–98.6%, indicating the presence of several phylogenetically defined clusters (Figure 19 in the *Actinomyces* chapter), which are separated by intra-cluster similarity values ranging from 95.4–97.4% to 95.3–98.6%. The idea that the genus *Arcanobacterium* may not represent a monophyletic taxon has been expressed before by Lehnen et al. (2006). Chemotaxonomic properties were demonstrated to correlate well with the phylogenetic structure in other actinobacterial genera. In general, the quinone system is a rather conserved characteristic. The finding of MK-10(H_4) in one lineage within the genus *Arcanobacterium*, represented by *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi*, and *Arcanobacterium pyogenes*, is rather exciting because the representatives of the second lineage, *Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pluranimalium*, are characterized by having the MK-9(H_4) quinone system. Hence, both quinone systems and phylogeny indicate that a subdivision of the genus *Arcanobacterium* might be appropriate, which would result in the restriction of the genus *Arcanobacterium* to the species *Arcanobacterium haemolyticum*, *Arcanobacterium phocae*, and *Arcanobacterium pluranimalium*. This would require the reclassification of *Arcanobacterium abortisuis*, *Arcanobacterium bernardiae*, *Arcanobacterium bialowiezense*, *Arcanobacterium bonasi*, and *Arcanobacterium pyogenes* in a novel genus. In a reclassified genus *Arcanobacterium*, the presence of a MK-9(H_4) quinone system might be a genus-specific trait, while MK-10(H_4) might characterize the neighboring genus. The suitability of the quinone system as the basis for such differentiation is supported by cluster-specific nucleotides, which can be considered a molecular signature (Table 12).

From a phylogenetic point of view, *Arcanobacterium hippocoleae* appears to be a phylogenetic neighbor of subcluster 1, while this species branches adjacent to *Arcanobacterium pluranimalium* (Figure 19 in the *Actinomyces* chapter), shows 95.1–95.8% sequence similarities (in contrast to 94.0–95.0% sequence similarities to members of subcluster 2) and shares six signature nucleotides that are common to members of subcluster 1. Although the branching of *Arcanobacterium hippocoleae* with members of subcluster 1 is supported by 87% bootstrap, the level at which this clustering be considered a taxonomically coherent entity should be decided on the basis of results of chemotaxonomic investigations.

Identification and descriptive characteristics of *Arcanobacterium* species

The phenotypic characteristics useful for identification of the recognized *Arcanobacterium* species are given in Table 14.

List of species of the genus *Arcanobacterium*

1. **Arcanobacterium haemolyticum** (MacLean, Liebow and Rosenberg 1946) Collins, Jones, and Schofield 1983, 438[VP] (*Corynebacterium haemolyticum* MacLean, Liebow and Rosenberg 1946, 69)

hae.mo.ly′ti.cum. Gr. neut. n. *haema* blood; N.L. adj. *lyticus -a -um* (from Gr. adj. *lutikos -ê -on*) able to loosen, able to dissolve; N.L. neut. adj. *haemolyticum*, blood-dissolving, hemolytic.

Surface colonies on blood agar are small (0.75 mm in diameter) after 24 h, becoming large (1.5–2.5 mm in diameter) on extended incubation. Colonies are circular discoid and slightly raised, and β-hemolytic. Growth is sparse on ordinary media but is enhanced by blood or serum. Slender, irregular rods predominate during the first 18 h on blood agar; many cells exhibit V-forms. Upon extended incubation, organisms become granular and segmented, and resemble small irregular cocci. On Loeffler's medium, they maintain the slender, irregular, bacillary form, but become pleomorphic at 48 h, with numerous club and comma forms. Facultatively anaerobic. Growth is considerably enhanced in an atmosphere of CO_2. The optimum temperature for growth is 37°C. The organism will not withstand heating at 60 °C for 15 min. Acid is produced from glucose, lactose and some other sugars. Catalase is negative. Extracellular DNase is produced. Gelatin, esculin, and casein are not hydrolysed. β-Galactosidase and *N*-acetyl-β-glucosaminidase are produced, but β-glucuronidase and α-fucosidase are not. The organism is resistant to oxytetracycline (30 pg per disc). The interpeptide bridge within the peptidoglycan is L-Lys–L-Lys–D-Glu (Type A5α). The principal menaquinone is MK-9(H_4).

The type strain was isolated from infections amongst American soldiers.

DNA G+C content (mol%): 50–52 (T_m).

Type strain: ATCC 9345, CIP 103370, DSM 20595, IFO (now NBRC) 15585, LMG 16163, NCTC 8452.

Sequence accession no. (16S rRNA gene): AJ234059.

2. **Arcanobacterium abortisuis** Azuma, Murakami, Ogawa, Okada, Miyazaki and Makino 2009, 1471[VP]

a.bor.ti.su′is. L. n. *abortus, abortus* an abortion; L. n. *sus, suis* a pig, a sow; N.L. gen. n. *abortisuis* from an abortion of a sow.

Cells are short and diphtheroid-shaped and are arranged in either V-forms or palisades. Colonies have a translucent smooth surface and are strictly anaerobic. Good growth also occur under aerobic conditions. Catalase- and indole-negative. Reduces nitrate. Soluble starch is hydrolyzed, but gelatin is not. The CAMP-test is negative. Produces acid from adonitol, cellobiose, fructose, galactose, glucose, glycerol, inulin, lactose, maltose, melezitose, raffinose, sucrose, soluble starch, and trehalose. Does not ferment amygdalin, arabinose, arbutin, dulcitol, erythritol, inositol, mannitol, mannose, melibiose, rhamnose, ribose, salicin, sorbitol, sorbose or xylose.

Produces α-galactosidase, β-galactosidase, α-glucosidase, and leucine arylamidase but not urease, β-glucosidase or pyroglutamic acid arylamidase. Fermentation end products are lactic, succinic, and acetic acids. Whole-cell sugars include rhamnose and ribose. Cell-wall peptidoglycan contains glutamic acid, alanine and lysine in the molar ratio of 1:2:1. Major fatty acids are $C_{14:0}$, $C_{16:1}$ ω7, $C_{16:0}$ and $C_{18:1}$ω9. The major menaquinone is MK-10(H_4). Polar lipids are phosphatidylethanolamine and two unknown phosphatidylinositol mannosides. The interpeptide bridge within the peptidoglycan has not been reported.

The type strain was isolated from a sow's placenta after an abortion.

DNA G+C content (mol%): 63.8 (HPLC).

Type strain: Murakami, ATCC BAA-1522, DSM 19515, JCM 14813.

Sequence accession no. (16S rRNA gene): AB305159.

3. **Arcanobacterium bernardiae** (Funke, Pascual Ramos, Fernández-Garayzábal, Weiss and Collins 1995), comb. nov. Pascual Ramos, Foster and Collins 1997b, 51[VP] (*Actinomyces bernardiae* Funke, Pascual Ramos, Fernández-Garayzábal, Weiss and Collins 1995, 59)

ber.nar.di′a.e. N.L. gen. fem. n. *bernardiae* of Bernard, named after the contemporary Canadian microbiologist Kathryn A. Bernard for her contributions to the study of asporogenous, Gram-positive rods.

Cells are gram-positive rods, with coccobacilli predominating. Cells are sometimes arranged in clusters, but primary branching is not observed. Cells are non-motile and do not form spores. Colonies are circular, smooth, and slightly convex with a glassy appearance. Colony diameters range from 0.2 to 0.5 mm after 48 h of incubation in the presence of 5% CO_2 on sheep blood agar. Facultatively anaerobic. Catalase is not produced. Acid is produced from adonitol, D-arabitol, D-fructose, D-glucose, glycerol, maltose, ribitol, starch, xylitol, and 5-keto-gluconate. Most strains ferment L-arabitol, erythritol, glycogen, and ribose. Acid is not produced from amygdalin, arbutin, xylose, mannitol, α-methyl-D-mannoside, sucrose, and 2-ketogluconate. Leucine arylamidase and α-glucosidase positive. Alkaline phosphatase, cystine arylamidase, chymotrypsin, trypsin, acid phosphatase, α-galactosidase, β-glucuronidase, β-glucosidase, α-mannosidase, and α-fucosidase negative. Esculin and urea are not hydrolyzed. Nitrate is not reduced. Palmitic and stearic acids are the main straight-chain cellular fatty acids, while oleic acid is the predominant unsaturated fatty acid. The major menaquinone is MK-10(H_4). The interpeptide bridge within the peptidoglycan is L-Lys–L-Ala–L-Lys–D-Glu (type A5α).

The type strain was isolated from human blood.

DNA G+C content (mol%): 63–66 (T_m).

Type strain: LCDC 89–0504, CCUG 33419, CIP 104252, DSM 9152, LMG 18721.

Sequence accession no. (16S rRNA gene): X79224.

4. **Arcanobacterium bialowiezense** Lehnen, Busse, Frölich, Krasinska, Kämpfer and Speck 2006, 864[VP]

bi.a.lo.wi.e.zen′se. N.L. neut. adj. *bialowiezense* of or pertaining to Bialowieza, Poland, where the type strain was isolated.

Cells are short pleomorphic rods. After 48 h of growth under aerobic conditions on sheep blood agar, colonies are translucent, convex, approximately, 0.5 mm in diameter and surrounded by a narrow zone of β-hemolysis. Cells are non-motile (motility agar), facultatively anaerobic and are catalase- and oxidase-negative. Best growth occurs at 37°C; no growth at 42°C. No growth is observed on Gassner or MacConkey agar. Nitrate reduction is negative. Hydrolysis of gelatin and esculin negative. Hippurate hydrolysis is positive. The CAMP-test is negative. Acid is produced from D-fructose, D-glucose, and glycerol. Acid is not produced from adonitol, D-arabitol, L-arabitol, erythritol, glycogen, inulin, D-lactose, maltose, D-mannitol, raffinose, ribose, D-sorbitol, starch, sucrose, trehalose, and D-xylose. Acid phosphatase, esterase lipase (C8), naphthol-AS-BI-phosphohydrolase, β-glucuronidase, α-glucosidase and pyrazinamidase positive. Alkaline phosphatase, cystine arylamidase, chymotrypsin, α-galactosidase, *N*-acetyl-β-glucosaminidase, β-glucosidase, α-fucosidase, leucine arylamidase, α-mannosidase, pyrrolidonyl arylamidase, trypsin and urease negative. The quinone system contains MK-10(H_4) as the predominant compound. The interpeptide bridge within the peptidoglycan has not been reported.

Source (type strain): prepuce of a European bison.

DNA G+C content (mol%): not reported.

Type strain: 1(W3/01), DSM 17162, NCTC 13354.

Sequence accession no. (16S rRNA gene): AJ879696.

5. **Arcanobacterium bonasi** Lehnen, Busse, Frölich, Krasinska, Kämpfer and Speck 2006, 864[VP]

bo. na′ si. L. n. *bonasus*, *-i* a species of bull in Pœonia, with the hair of a horse, and with horns unfit for fighting; L. gen. n. *bonasi* of *bonasus*, of the European bison (*Bison bonasus*) from which the type strain was isolated.

Cells are short pleomorphic rods. After 48 h of growth under aerobic conditions on sheep blood agar, colonies are translucent, convex, approx. 0·5 mm in diameter and surrounded by a narrow zone of β-hemolysis. Cells are non-motile (motility agar), facultatively anaerobic and catalase- and oxidase-negative. Best growth occurs at 37°C; no growth at 42°C. No growth is observed on Gassner or MacConkey agar. Nitrate reduction is negative. Hydrolysis of gelatin and esculin negative. Hippurate hydrolysis is positive. The CAMP-test is negative. Acid is produced from D-arabitol, L-arabitol, D-fructose and trypsin. Acid is weakly produced from adonitol, erythritol, and glycerol. Acid is not produced from erythritol, D-glucose, glycogen, inulin, D-lactose, maltose, D-mannitol, raffinose, ribose, D-sorbitol, starch, sucrose, trehalose, and D-xylose. Acid phosphatase, esterase lipase (C8), lipase (C14), naphthol-ASBI-phosphohydrolase, β-glucuronidase, pyrazinamidases, and pyrrolidonyl arylamidase positive. Alkaline phosphatase, cystine arylamidase, chymotrypsin, α-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-fucosidase, leucine arylamidase, α-mannosidase, and urease negative. The quinone system contains MK-10(H_4) as the predominant compound. The interpeptide bridge within the peptidoglycan has not been reported.

Source (type strain): prepuce of a European bison.

DNA G+C content (mol%): not reported.

Type strain: 2(W106/04), DSM 17163, NCTC 13355,

Sequence accession no. (16S rRNA gene): AJ879697.

6. **Arcanobacterium hippocoleae** Hoyles, Falsen, Foster, Rogerson and Collins 2002b, 619[VP]

hip.po.co.le'a.e. Gr. masc. and fem. n. *hippos* horse; Gr. masc. n. *koleos* sheath, vagina; N.L. masc. gen. n. *hippocoleae* of the horse vagina.

Cells are non-branching, irregular-shaped rods which stain Gram-positive, are non-acid-fast and non-motile. Colonies on blood agar are convex, circular, entire, shiny, opaque and grey. Weakly hemolytic. Facultatively anaerobic and catalase-negative. Acid is produced from D-glucose and lactose, but not from D-arabitol, L-arabinose, cyclodextrin, glycogen, pullulan, mannitol, melibiose, melezitose, methyl β-D-glucopyranoside, D-ribose, D-raffinose, sucrose, D-sorbitol, tagatose, trehalose or D-xylose. Acid may or may not be produced from maltose depending on the test system used. α-Glucosidase, β-galactosidase, β-glucuronidase, leucine arylamidase, and phosphoamidase are detected, but not acid phosphatase, alanine phenylalanine proline arylamidase, arginine dihydrolase, chymotrypsin, esterase C-4, ester lipase C8, α-fucosidase, α-galactosidase, β-glucosidase, lipase C14, α-mannosidase, β-mannosidase, pyrolidonyl arylamidase, pyroglutamic acid arylamidase, pyrazinamidase, trypsin, valine arylamidase, urease or glycyl tryptophan arylamidase. *N*-Acetyl-β-glucosaminidase and alkaline phosphatase may or may not be detected depending on the test system used. Esculin (weak reaction) and hippurate are hydrolysed, but not gelatin. Acetoin is not produced. Nitrate is not reduced to nitrite.

Habitat is not known.

Source (type strain): vaginal discharge from a horse.

DNA G+C content (mol%): not reported.

Type strain: M401624/00/2, CCUG 44697, CIP 106850, DSM 15539.

Sequence accession no. (16S rRNA gene): AJ300767.

7. **Arcanobacterium phocae** Pascual Ramos, Foster and Collins 1997b, 52[VP]

pho'ca.e. L. gen. n. *phocae* of a seal, isolated from common seals (*Phoca vitulina*) and grey seals (*Halichoerus grypus*).

Cells are coccobacilli and short rods that occur singly, in pairs, or in clusters; primary branching is not observed. Short diphtheroid forms may occur. Gram-stain-positive, non-motile, non-spore-forming, non-acid-fast. Colonies on blood agar (incubated for 24 h) are white, tiny, circular, low convex and surrounded by a zone of β-hemolysis which may be two to three times the diameter of the colony. Facultatively anaerobic. Growth is not enhanced by increased concentrations of CO_2, (5–10%). Catalase reaction is variable. Metabolism is strictly fermentative. Acid but not gas is produced from glucose. Acid is produced from D-fructose, galactose, D-glucose, N-acetylglucosamine, glycerol, glycogen, lactose, maltose, D-ribose, starch, sucrose, D-turanose, and 5-keto-gluconate. Most strains ferment inositol, mannose, melezitose, and trehalose, and a few strains ferment gluconate, mannitol, D-tagatose, and D-xylose. Acid is not produced from adonitol, amygdalin, D-arabinose, L-arabinose, D-arabitol, L-arabitol, cellobiose, dulcitol, erythritol, D-fucose, L-fucose, gentiobiose, 2-keto-gluconate, α-methyl-D-glucoside, D-lyxose, rhamnose, salicin, D-sorbitol, sorbose, α-methyl-mannoside, arbutin, melibiose, inulin, D-raffinose, L-xylose, β-methyl-D-xyloside, and xylitol. Nitrate reduction is negative. Esculin, gelatin, and urea are not hydrolyzed. Acid phosphatase, alkaline phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, pyrazinamidase, esterase (C4), esterase-lipase (C8), cystine arylamidase, and leucine arylamidase are produced. Production of trypsin is variable. Chymotrypsin, β-glucosidase, *N*-acetyl-β-glucosaminidase, β-glucuronidase, α-fucosidase, α-mannosidase lipase (C14), naphthol-AS-BI-phosphohydrolase, pyrrolidonyl arylamidase, and valine arylamidase are not produced. The interpeptide bridge within the peptidoglycan is L-Lys–Lys-D-Glu (Type A5α). The principal menaquinone is MK-9(H_4).

Arcanobacterium phocae has been isolated from various tissues and fluids of common seals (*Phoca vitulina*) and grey seals (*Halichoerus grypus*), for which its pathological significance is unclear, but it has been recovered in mixed cultures from pneumonic and septicemic seals.

Source (type strain): the lung of common seals (*Phoca vitulina*).

DNA G+C content (mol%): not reported.

Type strain: M1590/94/3, CIP 105740, DSM 10002, LMG 18722. The type strain possesses the characteristics of the species except that it is Catalase-positive and produces trypsin. M1590/94/3 ferments inositol, mannitol, mannose, melezitose, trehalose, and D-xylose but does not ferment D-tagatose and gluconate.

Sequence accession no. (16S rRNA gene): EU1945657.

Additional remarks: the type strain possesses the characteristics of the species except that it is catalase-positive and produces trypsin. M1590/94/3 ferments inositol, mannitol, mannose, melezitose, trehalose, and D-xylose but does not ferment D-tagatose and gluconate.

8. **Arcanobacterium pluranimalium** Lawson, Falsen, Foster, Eriksson, Weiss and Collins 2001a, 58[VP]

plur.a.ni.ma'li.um. L. comp. adj. *plus, pluris* more, a greater quantity; L. gen. pl. n. *animalium* from animals; N.L. gen. pl. n. *pluranimalium* from many animals.

Cells are straight to slightly curved, non-branching, slender rods which stain Gram-positive, are non acid fast and non-motile. Facultatively anaerobic and catalase-positive. Acid is produced from D-glucose and D-ribose, but not from D-arabitol, L-arabinose, cyclodextrin, glycogen, pullulan, lactose, mannitol, melibiose, melezitose, raffinose, D-sorbitol, sucrose, tagatose, trehalose or D-xylose. Maltose is variable. Alanine phenylalanine proline arylamidase, pyroglutamic acid arylamidase and β-glucuronidase are detected, but not alkaline phosphatase, arginine dihydrolase, α-galactosidase, β-galactosidase, β-galacturonidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, β-mannosidase or urease. Pyrazinamidase and glycyl tryptophan arylamidase may or may not be detected. Esculin (weak reaction), gelatin and hippurate are hydrolyzed. Acetoin is not produced. Nitrate is not reduced to nitrite. The interpeptide bridge within the peptidoglycan is L-Lys–Lys-D-Glu (type A5α). The principal menaquinone is MK-9(H_4).

Habitat is not known.

Source (type strain): a dead harbor porpoise and a dead sallow deer.

DNA G+C content (mol%): 57 (method not reported).

Type strain: M430/94/2, CCUG 42575, CIP 106442, DSM 13483.

Sequence accession no. (16S rRNA gene): AJ250959.

9. **Arcanobacterium pyogenes** (Glage 1903), Pascual Ramos, Foster and Collins 1997b, 51[VP] [*Bacillus pyogenes* Glage 1903, 1973; *Corynebacterium pyogenes* (Glage) Eberson 1918, 23; *Actinomyces pyogenes* Reddy, Cornell and Fraga 1982, 427]

py.o′ge.nes. Gr. neut. n. *pyon* pus; N.L. suff. *-genes* (from Gr. v. *gennaô* to produce) producing; N. L. adj. *pyogenes* pus-producing).

Gram-stain-positive, nonmotile, non-spore-forming coccobacilli and short rods that occur singly, in pairs (V, T, and palisade formations), or in clusters. Short diphtheroid forms with clubs are also seen. Streptococcal forms in small clumps and short crooked chains are occasionally observed. Cells vary in shape and size (0.2–0.9 by 0.3–2.5 μm) in different media. Cells from 24-h-old broth cultures are Gram-stain-positive, but cells from older cultures may be Gram-stain-variable. The cell-wall ultrastructure is typical of Gram-stain-positive bacteria. The cell walls are 29 to 30 nm thick and have a characteristic double-track appearance. Pinpoint, β-hemolytic colonies occur on sheep blood agar after 24 h of incubation. The zones of hemolysis are typically two to three times the diameter of the colony. After 48–72 h, the colonies (diameter 0.5–1.5 mm) are convex, circular, opaque, white, and soft with entire edges. Colonies develop faster and are bigger (diameter 1.5–3.0 mm) on SFM agar plates. Good growth occurs under aerobic and strictly anaerobic conditions. Metabolism is strictly fermentative. Acid but not gas is produced from cellobiose, dextrin, fructose, galactose, glucose, glycogen, lactose, maltose, mannose, melezitose, starch, trehalose, and xylose. The fermentation of adonitol, arabinose, erythritol, glycerol, sucrose, mannitol, and sorbitol varies with the strain. No acid is produced from amygdalin, esculin, melibiose, raffinose, rhamnose, or salicin. Alanine, arginine, aspartate, glycine, and threonine are not fermented. Most strains are catalase-negative, although one strain has been reported to be catalase-positive. Acid clotting and digestion of clots in litmus milk and liquefaction of gelatin are characteristic of all strains. Nitrates are not reduced, and indole is not produced. The optimum growth temperature is 37°C; the temperature range is 20–40°C.

Lactic acid is the primary metabolic product in brain heart infusion or tryptose broth with no added HCO_3^-; acetate is a minor product. Glucose is fermented in the presence of CO_2/HCO_3^- and this reaction yields succinate, acetate, formate, and lactate as major end products. For each mol of CO_2/HCO_3^- fixed, 1 mol of succinate, 1 mol of acetate, and 1 mol of formate are produced. In identical media without added bicarbonate or hemin, lactate is the major product, and smaller amounts of acetate, succinate, and formate are produced. CO_2/HCO_3^- is required for growth. Hemin is highly stimulatory or required for growth. Peptides are required for growth even in the presence of a complete complement of 20 amino acids and $(NH_4)_2SO_4$. Inositol can replace the peptide requirement for growth. Riboflavin and nicotinic acid are required for optimal growth. Adenine and uracil are required for optimal growth of some strains. Characteristic cell-wall sugar components are rhamnose and glucose. No mycolic acids are present. Culture filtrates are fatal to mice and rabbits after intravenous injection. The soluble hemolysin produced is active against human, guinea pig, sheep, horse, and rabbit erythrocytes. Both toxic and hemolytic activities of crude cell extracts are neutralized by antitoxin. The interpeptide bridge within the peptidoglycan is L-Lys–L-Ala–L-Lys–D-Glu (type A5α). The principal menaquinone is MK-10(H_4).

This organism is frequently isolated from a wide variety of pyogenic disease conditions in many species of domestic animals and in humans. Presumably, *Arcanobacterium pyogenes*, occurs as a commensal organism on the mucous surfaces of warm-blooded animals.

DNA G+C content (mol%): 56–58 (T_m).

Type strain: C-100, ATCC 1941, CCUG 13230, CIP 103129, DSM 20630, LMG 16162, NCTC 5224.

Sequence accession no. (16S rRNA gene): X79225.

Genus IV. **Mobiluncus** Spiegel and Roberts 1984a, 180[VP] emend. Hoyles, Collins, Falsen, Nikolaitchouk and McCartney 2004

LESLEY HOYLES AND ANNE L. MCCARTNEY

Mo.bi.lun′cus. L. adj. *mobilis* capable of movement, active; L. masc. n. *uncus* hook; N.L. masc. n. *Mobiluncus* a motile curved rod.

Curved rods with tapered ends, 1–5 × 0.4–0.6 μm. Depending on the growth medium, cells occur singly or in pairs with a gull-wing appearance. **Gram-stain-negative or Gram-stain-variable**. Cells are **motile** by means of **multiple subpolar flagella** (exact numbers are yet to be determined, but are thought to be between one and eight), and possess a multi-layered Gram-stain-positive cell-wall type. **Endospores are not formed**. **Anaerobic**, growing best in an enriched CO_2 atmosphere. Some strains become aerotolerant after several passages, being able to grow in a partially reduced atmosphere containing 5% O_2. Optimum growth at 35–37°C, with no or poor growth at 20, 43, or 45°C. Growth is stimulated by horse or rabbit serum and by whole blood. Growth is not stimulated by formate/fumarate. Slow growth on solid media. After 3 d incubation at 37°C, colonies on peptone/yeast extract/glucose/sheep blood or Columbia agar supplemented with human blood are pin-point to 1 mm in diameter. After 5 d, the colonies are larger, 1–2.5 mm in diameter, and gray-white or slightly yellowish. Cells are killed by heating at 55°C for 15 minutes. **Oxidase- and catalase-negative**. Weakly (terminal pH 5.5–6.5) or strongly (terminal pH <5.5) saccharolytic. Fermentation products include acetic and succinic acids, with or without lactic acid, when grown in peptone/yeast extract/glucose medium. Propionic acid is not produced. Do not produce acid from L-arabinose, D-arabitol, lactose, mannitol, methyl-β-D-galactopyranoside, or sorbitol. Negative for alkaline phosphatase, α-arabinosidase,

chymotrypsin, β-galactosidase-6-phosphate, β-glucosidase, trypsin, and urease (RapID 32Strep), cysteine arylamidase, lipase (C14), α-mannosidase, β-mannosidase, *N*-acetyl-β-glucosaminidase, glutamyl glutamic acid arylamidase, pyroglutamic acid, and valine arylamidase activity. Variable activity for phenylalanine arylamidase (weak- to strong-positive reaction). **Acid phosphatase- and pyrollydonyl arylamidase-negative**. **Acetoin is not produced**. Gelatin is not hydrolyzed. **Nitrate may be reduced**. Sensitive to ampicillin, cefazolin, cefoxitin, cephalothin, clindamycin, gentamicin, imipenem, moxalactam, penicillin G, rifampin, streptomycin, tobramycin, vancomycin, and virginiamycin. Resistant to colistin, cycloserine, nalidixic acid, neomycin, and mezlocillin. Associated with the human vaginal flora and bacterial vaginosis (BV).

DNA G+C content (mol%): 49–52 (T_m; Spiegel and Roberts, 1984a); 50–54 (T_m; Hammann et al., 1984).

Type species: **Mobiluncus curtisii** Spiegel and Roberts 1984a, 181[VP].

Further descriptive information

Phylogeny. Partial reverse transcriptase sequencing of the 16S rRNA from *Mobiluncus curtisii* and *Mobiluncus mulieris* and subsequent sequence analysis led Lassnig et al. (1989) to conclude that the genus *Mobiluncus* belonged to the order *Actinomycetales*, not to the family *Bacteroidaceae* (as assigned by Spiegel and Roberts, 1984a), and that the species were moderately related to the genus *Actinomyces*. More recent analyses have confirmed that the genus *Mobiluncus* shares common ancestry with the two subspecies of [*Actinomyces*] *neuii* (Pascual Ramos et al., 1997b) and with *Varibaculum cambriense* (Hoyles et al., 2004), but the relationships are not statistically significant (Hall et al., 2003e; Hoyles et al., 2004; Pascual Ramos et al., 1997b). Sequence divergence values among these taxa of between 10 and 11% indicate that they represent three distinct bacterial lineages. Schaal et al. (2006) have suggested that the family *Actinomycetaceae* should be considered to comprise six phylogenetic clusters, with *Mobiluncus* spp. belonging to cluster 4. Assignment to specific clusters is based upon cut-off branching points and signature nucleotides of 16S rRNA gene sequences (Schaal et al., 2006; Stackebrandt et al., 1997).

Cell-wall composition. Although they observed that the Gram reactions of *Mobiluncus* spp. vary with age of culture and species, Spiegel and Roberts (1984a) noted that electron micrographs of both species revealed multi-layered Gram-stain-positive cell walls without an outer membrane. They postulated that the thinness of the peptidoglycan layer may explain the tendency of the curved, rod-shaped organisms to stain Gram-negative. Carlone et al. (1986) demonstrated the presence of peptidoglycan by analyzing *o*-methyloxime acetate derivatives of whole-cell carbohydrates of four strains of *Mobiluncus*. No 2-keto-3-deoxy-octulosonic acid (KDO) or degradation products of KDO were present in either species, nor was L-glycero-D-mannoheptose (heptose), consistent with a Gram-stain-positive cell-wall type. Comparable amounts of galactose, glucosamine, muramic acid, and rhamnose were observed in both species. Three times as much ribose was present in *Mobiluncus mulieris* strains as in *Mobiluncus curtisii* strains, whereas *Mobiluncus curtisii* strains had twice as much glucose as *Mobiluncus mulieris*. Mannosamine was present in *Mobiluncus curtisii* subsp. *curtisii* (4%) and *Mobiluncus curtisii* subsp. *holmesii* (2%), but was absent from *Mobiluncus mulieris*. Galactosamine was present in *Mobiluncus mulieris* (1%) and *Mobiluncus curtisii* (0.5%). A relatively large amount of an unidentified compound was also found in the two *Mobiluncus mulieris* strains studied. Diaminopimelic acid was not detected in cell-wall hydrolysates of either species (Hammann et al., 1984). Lipopolysaccharide was absent from the cell wall (Carlone et al., 1986).

Fatty acids. Hydroxylated fatty acids are absent from the cell walls of *Mobiluncus* spp. (Carlone et al., 1986; Spiegel and Roberts, 1984a). The major cellular fatty acids include $C_{16:0}$ (hexadecanoic), $C_{18:2}$ (octadecadienoic), and $C_{18:1}$ (octadecenoic), representing greater than 50% of the total fatty acids; $C_{14:0}$ (myristic), $C_{16:1}$ (hexadecenoic), $C_{17:0}$ (heptadecanoic), and $C_{18:0}$ (octadecanoic) are also present (Carlone et al., 1986; Christiansen et al., 1984; Skarin et al., 1982, 1984b). The presence of fatty acid aldehydes needs further investigation, as there is conflicting evidence regarding their presence (Skarin et al., 1982) or absence (Carlone et al., 1986).

Flagella. Flagella have been observed in electron micrographs of both *Mobiluncus* species, although the exact number is yet to be determined. Curtis (1913) noted that *Mobiluncus* spp. were motile by means of up to six flagella, and that exposure to air led to a decrease in the motility of the organisms. Moore (1954) observed motility in two strains isolated from women attending fertility clinics; the strains had up to six flagella, but were overgrown by contaminants before they were investigated further. He also collected ten strains that were motile by means of a single flagellum. Moore (1954) stated that the most distinctive morphological property of the organisms studied was their corkscrew motion. In all strains investigated, he found that the organisms were monotrichate, with a flagellum attached at or very near one pole, or in the center of the concave side of the organism, though most cultures showed occasional forms with two flagella in one or other of these positions. Moore (1954) also noted that the organisms became nonmotile after exposure to air and rapidly adhered to cellular debris, so that epithelial cells in particular were often furred with large numbers of immobilized vibrios ("clue cells"). Spiegel and Roberts (1984a) observed clusters of two to six flagella; sometimes a subterminal attachment site was observed. *Mobiluncus curtisii* has one to six flagella per cell with a common point of origin, while *Mobiluncus mulieris* has one to eight flagella with multiple origins (Hammann et al., 1984; Hernández et al., 1994; Sprott et al., 1983, 1984; Taylor and Owen, 1984). Pili (fimbriae) have not been observed (Hammann et al., 1984).

Colonial and cultural characteristics. On blood agar after 5 d incubation, colonies of *Mobiluncus mulieris* are small (<1 mm in diameter), convex, glossy, and colorless (Hernández et al., 1994). On Columbia agar base containing human blood (5%) and vitamin K_1 (1 mg/l), colonies are minute and transparent gray after anaerobic incubation for 48 h (Sprott et al., 1983): *Mobiluncus mulieris* strains produce α-hemolysis after prolonged culture on this medium, and develop a dark-brown pigment after 10–14 d incubation. Clinical isolates grown on Rlk and SA media containing laked rabbit blood (Smith and Moore, 1988) form colonies that are very small (0.25 mm, *Mobiluncus mulieris*; 0.32–0.35 mm, *Mobiluncus curtisii*), convex, glossy, and translucent after 48 h incubation; reference strain colonies

have a similar appearance when grown on these agars, but have much larger diameters (0.70–0.75 mm, *Mobiluncus mulieris*; 0.98–1.0 mm, *Mobiluncus curtisii*). When laked sheep blood is used instead of rabbit blood, 7 d incubation are required to achieve the diameters indicated for rabbit blood. On brain heart infusion, Brucella, and Wilkins–Chalgren agars supplemented with 5% horse blood, strains produce colonies that are small (1–2 mm diameter), slightly convex, entire, and transparent (Vetere et al., 1987): the colony morphology of *Mobiluncus curtisii* and *Mobiluncus mulieris* is indistinguishable, but β-hemolysis develops around *Mobiluncus mulieris* colonies more often than *Mobiluncus curtisii* colonies

Nutrition and growth conditions. *Mobiluncus* spp. require anaerobic conditions for growth (Hammann et al., 1984; Spiegel and Roberts, 1984a). After primary isolation and multiple passages, growth has been reported in 10% CO_2 or 5% O_2 (Hammann et al., 1984). The organisms are fastidious. Details of media (solid and broth) used to successfully isolate and culture *Mobiluncus* spp. can be found in the Enrichment and Isolation Procedures section of this chapter. Optimum growth is achieved at 35–37°C (Hammann et al., 1984; Spiegel and Roberts, 1984a).

Antibodies. One of the earliest studies into the use of polyclonal antibodies (pAbs) to distinguish strains of *Mobiluncus* spp. from one another was carried out by Moi et al. (1984b). They used hyperimmune rabbit pAbs to demonstrate the heat-labile and heat-stable antigens of *Mobiluncus curtisii* and *Mobiluncus mulieris*, and to study the antigenic relationship of these micro-organisms and other bacteria. Co-agglutination assays were used to demonstrate surface-specific antigens of the two species, and immunofluorescence assays were used to study the immunomorphology of the organisms. The main conclusions of their study were that the species could be separated into two distinct biochemical and serological groups, and that the antigenic markers of *Mobiluncus* spp. could be used in taxonomic, ecological, and epidemiological studies. Although they found differences in the heat-labile and heat-stable antigens of *Mobiluncus curtisii* and *Mobiluncus mulieris*, they did not investigate the potential of these antigens for the detection/identification of *Mobiluncus* spp. in routine diagnostic tests or in vaginal samples from patients with BV.

Since the study of Moi et al. (1984b), monoclonal antibodies (mAbs) have been used by a number of different groups to detect the presence of *Mobiluncus* spp. in vaginal samples and blood samples, and to detect strain differences among the two species and subspecies of the genus (Fohn et al., 1988; Hallén et al., 1987; Ison et al., 1989).

In a later study by Påhlson et al. (1986a), 51 strains of *Mobiluncus* from clinical isolates were studied using phenotypic traits and a set of mAbs to defined *Mobiluncus* antigens. Analysis of the phenotypic and mAb reactivity data showed that the strains could be split into two distinct species, *Mobiluncus curtisii* and *Mobiluncus mulieris*. However, Påhlson et al. (1986a) also noted strain variation. To give a better definition of the cell-wall proteins that differed between strains of *Mobiluncus*, a number of hybridomas secreting mAbs were constructed. The mAbs produced were shown to be specific to the genus *Mobiluncus*, as they did not react with *Bacillus cereus*, *Bacteroides fragilis*, *Escherichia coli*, *Haemophilus influenzae*, *Klebsiella* sp., *Neisseria* sp., *Peptostreptococcus magnus*, *Propionibacterium acnes*, *Proteus mirabilis*, and a number of the lactic acid cocci. The reactivity of the mAbs with members of the genus *Mobiluncus* was examined by immunoblot analysis of the soluble preparations from the type strains of the *Mobiluncus* species used to prepare the mAbs. The proteins were separated by SDS-PAGE and the distinct differences between the *Mobiluncus curtisii*, *Mobiluncus mulieris*, and atypical strains were clearly observed, providing a fingerprint for each individual strain (Påhlson et al., 1986a). Upon blotting onto nitrocellulose membranes and enzyme assay, the authors detected specific mAbs for each species. The antigens had molecular masses of 78 kDa for *Mobiluncus curtisii* and 84–92 kDa for *Mobiluncus mulieris*. The proteinaceous nature of the antigens was confirmed by the detection of a drop in binding in the enzyme assay (decrease in optical density readings) when they were treated with pronase. After showing the specificity of their mAbs for members of the genus *Mobiluncus*, Påhlson et al. (1986a) used their mAbs to detect *Mobiluncus* spp. in clinical samples. A comparison of their results for the detection of *Mobiluncus* by mAbs or by examination of a wet smear showed high accord between the two methods for detection of *Mobiluncus* spp.

Hallén et al. (1987) used mAbs in a study (immunofluorescence microscopy) to detect *Mobiluncus* spp. in vaginal samples from women with BV. They provided the first evidence that detection of *Mobiluncus* spp. by mAbs was far more sensitive than the previously relied upon traditional methods (i.e., Gram stains of vaginal smears, direct examination of vaginal suspensions for the presence of curved motile rods), and also demonstrated that *Mobiluncus* spp. could be detected in women who did not show signs of BV. Of the 90 strains of *Mobiluncus* isolated from vaginal specimens, 44% were *Mobiluncus curtisii* and 34% were *Mobiluncus mulieris* (Hallén et al., 1987). In 21% of the cases, *Mobiluncus curtisii* and *Mobiluncus mulieris* were found together. Previously, Påhlson and Forsum (1985) had detected *Mobiluncus* spp. by the use of mAbs in the examination of vaginal smears by indirect immunofluorescence. They used five different mAbs to cover all known *Mobiluncus* phenotypes. In a study of 59 women attending a clinic for sexually transmitted diseases (STDs), they found that indirect immunofluorescence gave a 30% higher yield of *Mobiluncus* spp. than did conventional cultivation.

Fohn et al. (1988) used SDS-PAGE and immunoblotting to demonstrate production of four murine mAbs specific for an 82-kDa molecule of *Mobiluncus curtisii* subsp. *curtisii* and five antibodies that detected a major band of *Mobiluncus mulieris* at 93 kDa. To confirm the application of their panel of mAbs, the authors tested them against 25 *Mobiluncus* isolates from women with BV. They detected the presence of *Mobiluncus* spp. in 24 of the clinical isolates, and also used the mAbs to detect the presence of *Mobiluncus* spp. directly in the vaginal fluid of a patient with BV. The use of an immunofluorescence assay with the mAbs in the examination of the vaginal fluid sample revealed that the patient was harboring *Mobiluncus curtisii* subsp. *holmesii*; subsequent isolation confirmed this identification.

Fohn et al. (1988) also used murine mAbs against the ATCC type strains of *Mobiluncus curtisii* subsp. *curtisii*, *Mobiluncus curtisii* subsp. *holmesii* and *Mobiluncus mulieris* in an ELISA/indirect immunofluorescence assay. Four of the mAbs tested were subspecies-specific and reacted with *Mobiluncus curtisii* subsp. *curtisii*, but not with *Mobiluncus curtisii* subsp. *holmesii*; four others

were specific for *Mobiluncus mulieris*. The remaining antibodies tested showed some cross-reactivity with both subspecies of *Mobiluncus curtisii*, with one defining a common epitope of *Mobiluncus curtisii* subsp. *holmesii* and *Mobiluncus mulieris* (mAb F3F1). It was also shown that the mAbs tested were specific for *Mobiluncus,* as they did not react with a test panel of bacteria commonly isolated from the vaginas of healthy women or women with BV (e.g., *Bacteroides* spp., *Gardnerella vaginalis*, *Lactobacillus* spp., *Neisseria gonorrhoeae*, and *Peptostreptococcus saccharolyticus*).

An extensive study was carried out by Ison et al. (1989) of 37 *Mobiluncus curtisii* and 25 *Mobiluncus mulieris* strains (clinical samples and the NCTC type cultures for the three recognized species). The intention was to develop a rapid detection system for *Mobiluncus* spp. Initially, the strains were identified as *Mobiluncus* spp. if they were anaerobic, motile, Gram-stain-variable curved rods that were resistant to 5 μg of metronidazole. The two species were distinguished by their ability to reduce nitrate, to hydrolyze hippurate, and to ferment various carbohydrates, and were divided according to criteria set out by Spiegel and Roberts (1984a). They were also tested for enzyme activity using the API ZYM system. Following separation of the strains into their respective species, seven mAbs were produced after a single fusion of spleen cells from mice inoculated with each type strain. Four were chosen for further study on the basis of their reactivity with various strains of *Mobiluncus*. In immunofluorescence studies, three of the four mAbs showed reactivity against the type strains of *Mobiluncus curtisii*, but not against the type strain of *Mobiluncus mulieris* (mAb 179.1 showed equal activity against both subspecies of *Mobiluncus curtisii*, but at different titers; mAb 180.1 showed highest activity against *Mobiluncus curtisii* subsp. *curtisii*, whereas mAb 179.3 showed highest activity against *Mobiluncus curtisii* subsp. *holmesii*). The mAb 181.1 showed activity against *Mobiluncus mulieris*, but not against *Mobiluncus curtisii*. Overall, 100% sensitivity for *Mobiluncus curtisii* (both subspecies) was only achieved when all three reactive mAbs were used together. No relationship was found between the reactivity of the three mAbs and the results of the biochemical tests performed. With regard to the mAb raised against the type strain of *Mobiluncus mulieris* and reactive with only a small proportion of the clinical isolates tested, the authors concluded that antigenic heterogeneity in this species may limit the value of a single mAb. They also suggested that the non-reactive strains they had identified may have been atypical of the generally recognized *Mobiluncus mulieris* phenotype.

In a study designed specifically to investigate the use of mAbs against *Mobiluncus* spp. as a serological marker of BV (in pregnant women whose sexual history and vaginal microbiological data were available), Schwebke et al. (1996) screened sera for antibodies to *Mobiluncus* spp. by an indirect immunofluorescence assay. The frequency of women with IgG antibodies against *Mobiluncus curtisii* was 75%, which was higher than the authors had anticipated. This was attributed to nonspecificity of the detected antibody response or higher prevalence of BV than first anticipated. However, the demonstration that antibodies against *Mobiluncus curtisii* were completely removed by adsorption with *Mobiluncus curtisii*, but not by adsorption with *Mobiluncus mulieris*, strongly suggests that the antibodies were specific. Schwebke et al. (1996), Fohn et al. (1988), and Ison et al. (1989) agreed that the prevalence of BV was poorly defined, and that, if the true incidence of *Mobiluncus* spp. in BV and in normal women was to be determined, good detection systems would be necessary to overcome the problems associated with more classical (cultivation) techniques.

Gatti et al. (1997) obtained the antigenic profiles for 30 strains of *Mobiluncus* (22 *Mobiluncus curtisii* and 8 *Mobiluncus holmesii*) isolated from vaginal samples using mouse immune ascitic fluids (MIAFs) from mice immunized with the ATCC type strains for the genus. Initially, the 30 strains were split into *Mobiluncus curtisii* and *Mobiluncus holmesii* on the basis of biochemical tests (*Mobiluncus curtisii* positive for the presence of α-galactosidase and β-galactosidase and for hydrolysis of hippurate; *Mobiluncus holmesii* negative for all three tests). Division of the *Mobiluncus curtisii* strains into its two subspecies was based on nitrate reduction. SDS-PAGE profiles were obtained for each of the 30 strains and these were transferred to nitrocellulose membranes for blotting with the different MIAFs. The major antigenic proteins of *Mobiluncus curtisii* and *Mobiluncus mulieris*, as determined by their homologous MIAF, showed that *Mobiluncus curtisii* subsp. *holmesii* had five major antigenic proteins (63-, 54-, 52-, 46-, and 30-kDa bands), whereas *Mobiluncus curtisii* subsp. *curtisii* had only four of these antigenic proteins (no 54-kDa band). Of the 22 *Mobiluncus curtisii* samples tested, eight had the *Mobiluncus curtisii* subsp. *holmesii* pattern, whereas 14 had the *Mobiluncus curtisii* subsp. *curtisii* pattern. The authors found no correlation between the antigenic patterns of the vaginal isolates of *Mobiluncus curtisii* and the biochemical identification of the subspecies, because the antigenic patterns of the two subspecies were found to be interchangeable. *Mobiluncus mulieris* was shown to contain three major protein bands (64, 48, and 45 kDa), and a series of antigenic proteins (64–100 kDa). None of the clinical isolates of *Mobiluncus mulieris* gave identical profiles to that of the type strain. Gatti et al. (1997) also found cross-reactivity between the species and subspecies by immunoblot analysis with heterologous pAbs. Within the 22 isolates of *Mobiluncus curtisii* studied, only two different antigenic profiles were found based on the recognition, or lack, of a 54-kDa protein shown when *Mobiluncus curtisii* blots were probed with anti-*Mobiluncus curtisii* subsp. *holmesii* MIAF, whereas all of the *Mobiluncus mulieris* strains contained some major antigenic proteins of the type strain and showed great variability only in the 64–100-kDa antigenic proteins. However, *Mobiluncus curtisii* and *Mobiluncus mulieris* could be distinguished from each other by their antigenic protein profiles, particularly by the presence or absence of a 30- or 34-kDa protein.

In summary, antigenic characterization of *Mobiluncus* spp. with polyvalent rabbit antisera and mAbs has shown *Mobiluncus curtisii* and *Mobiluncus mulieris* to be fairly distinct, whereas the two subspecies of *Mobiluncus curtisii* show significant antigenic homogeneity. Also, the use of mAbs and pAbs to detect and identify *Mobiluncus* spp. is limited by the range of available antibodies. Ison et al. (1989) stated that, if mAbs are to be used successfully in studies to elucidate the role of *Mobiluncus* spp. in BV (and one would assume to detect and identify *Mobiluncus* spp. routinely), several antibodies will be required to detect the species and subspecies of the genus. The advantages of using mAb techniques over classical techniques are that they are simpler, less cumbersome, and less time-consuming. mAb techniques also allow for the selection of antigens specific to *Mobiluncus* in highly complex antigenic mixtures (Påhlson et al., 1986a).

Antibiotic sensitivity. Spiegel (1987) performed a standardized study of the sensitivity of 12 *Mobiluncus curtisii* strains and ten *Mobiluncus mulieris* strains to 23 antimicrobials and 15 other compounds known to inhibit bacterial growth: tests were done either by microbroth dilution (antimicrobial agents) or agar dilution (other agents). MIC ranges (μg/ml) are given in parentheses for *Mobiluncus curtisii* and *Mobiluncus mulieris*, respectively, where values are known for both species. All strains were sensitive to ampicillin (0.125–0.25 and ≤0.015–0.062), cefazolin (≤0.2–1.56 and ≤0.2–0.78), cefoxitin (1–4 and 0.25–0.5), cephalothin (0.78–1.56 and ≤0.2–0.4), chloramphenicol (4–8 and 2–4), clindamycin (0.062–0.125 and ≤0.015–4), imipenem (0.031–0.125 and 0.031–0.062), moxalactam (1–4 and ≤0.062–0.5), penicillin G (0.015–0.125 and 0.008–0.015), rifampin (≤0.004 and ≤0.004), tobramycin (0.25–1 and 0.25–1), vancomycin (0.5 and 0.5–1), and virginiamycin (≤0.2 and ≤0.2–0.39). All strains were resistant to colistin (32–64 and 64–256), cycloserine (≥200 and 100–>200), nalidixic acid (≥200 and 100–200), and neomycin (2–8 and 4–8). In addition, Hammann et al. (1984) demonstrated that both species were resistant to mezlocillin, slightly sensitive to gentamicin, and resistant to, or showed microcolony formation with, erythromycin and oxytetracycline. Sprott et al. (1983) also showed that *Mobiluncus curtisii* and *Mobiluncus mulieris* were sensitive to gentamicin (0.5–1.0 and 1.0–2 mg/l, respectively) and streptomycin (8–16 and 4–8 mg/l, respectively). The occurrence of aminoglycoside sensitivity in anaerobic organisms is rare, and its significance is unknown (Spiegel, 1987; Sprott et al., 1983). *Mobiluncus* spp. have also been shown to be sensitive to rifaximin (≤1 μg/ml; Hoover et al., 1993).

Mobiluncus curtisii was resistant to tinidazole (>256 μg/ml), while only one of ten strains of *Mobiluncus mulieris* was resistant to this antimicrobial (4–>256) (Spiegel, 1987). *Mobiluncus curtisii* strains were resistant to metronidazole (35–512) and hydroxymetronidazole (128–512); there was variability in the resistance of *Mobiluncus mulieris* strains to these two antimicrobials (2–>512 and 4–>512, respectively) (Spiegel, 1987). Sprott et al. (1983) also noted a difference in the sensitivity of *Mobiluncus curtisii* and *Mobiluncus mulieris* to metronidazole (0.5–4 mg/l and 16–1000 mg/l, respectively) but did not find increased activity of hydroxymetronidazole against their strains. The relative resistance of both species to metronidazole and tinidazole may aid in the development of selective media for the isolation of *Mobiluncus* spp. from clinical samples (Spiegel, 1987). However, some strains are inhibited by metronidazole (<8 μg/ml) (Hammann et al., 1984).

Spiegel (1987) also examined the effects of 15 compounds (alizarin red, azure II, basic fuchsin, brilliant green, deoxycholate, Evans blue, Gentian violet, Janus green, malachite green, methyl orange, Nile blue A, oxgall, resazurin, safranine, and sodium fluoride) known to inhibit growth of *Mobiluncus* strains. No quality control values were available for these compounds; therefore, no interpretations of sensitivity or resistance could be made. However, the information generated on these compounds may be of use in choosing selective agents for *in vitro* use (Spiegel, 1987). Of the 15 compounds tested, alizarin red, Evans blue, and sodium fluoride were found to inhibit *Mobiluncus mulieris* growth more than *Mobiluncus curtisii* growth. The use of sodium fluoride in selective media is limited, however, as it is a poison and cannot be placed in glass (Spiegel, 1987).

Only one study has been done regarding the presence of resistance determinants in *Mobiluncus* spp. Leng et al. (1997) examined *Mobiluncus curtisii* and *Mobiluncus mulieris* isolates for the presence of *tetQ* and *tetO*, encoding proteins that protect bacterial ribosomes from tetracycline both *in vivo* and *in vitro*. Five of the 12 *Mobiluncus curtisii* strains examined carried the *tetO* gene, two carried the *tetQ* gene, one carried both genes, and the remaining strains carried neither gene. Of the eight *Mobiluncus mulieris* strains examined, two carried *tetO*, two carried *tetQ*, one carried both genes, and three strains carried neither gene. Tetracycline resistance was observed in some of the strains that carried neither *tet* gene, suggesting that other novel tetracycline-resistance determinants are present in the genus *Mobiluncus*. One *Mobiluncus curtisii* strain is known to carry the *tetQ* gene on its chromosome (Leng et al., 1997).

Ecology

Association with BV. *Mobiluncus* spp. form part of the indigenous microbiota of the human vagina. Cultivation of strains from vaginal smears from healthy women often proves problematic, due to their fastidious nature and their overgrowth by less-fastidious, faster-growing organisms, such as *Lactobacillus* spp. (Hammann et al., 1984; Smith and Moore, 1988). However, the isolation of *Mobiluncus* spp. from vaginal samples from women afflicted by bacterial vaginosis (BV) has been well documented (Fontaine et al., 1982; Hjelm et al., 1982; Holst et al., 1982, 1984a; Skarin et al., 1984a; Sprott et al., 1982, 1983). It is thought that the increase in pH associated with the onset of BV allows less prominent members of the vaginal flora, such as *Mobiluncus* species, to become prominent. However, isolation of these organisms from BV samples is still difficult and their role, if any, in BV has not been determined: they are considered an indicator organism for BV, rather than the causative agent (Fox and Phillips, 1984; Hallén et al., 1987; Hjelm et al., 1984; Schwebke et al., 1996). Notably, *Mobiluncus* spp. are not present in all patients with BV (Hallén et al., 1987). Where *Mobiluncus* spp. are associated with BV, it is not unusual to detect both *Mobiluncus* species simultaneously (Hallén et al., 1987, 1988).

In addition to the detection of *Mobiluncus* spp. in BV-affected women, Hallén et al. (1987) also demonstrated the presence of *Mobiluncus* spp. in infections associated with candidal vaginitis (14 of 148 patients), chlamydial infection (14 of 65), gonorrhea (7 of 14), trichomoniasis (3 of 9), non-specific urethritis (3 of 21), and non-specific cervicitis (3 of 19).

Prevalence in healthy women. There are conflicting reports with regard to the prevalence of *Mobiluncus* spp. in vaginal secretions from healthy women. Older studies (Hallén et al., 1987; Skarin and Mardh, 1982; Sprott et al., 1983) show detection levels of up to 6%, whereas more recent conventional bacteriological studies have shown that the prevalence of *Mobiluncus* spp. in healthy women is 0.7–4% (Hillier et al., 1991). Using a PCR-based method, Schwebke and Lawing (2001) demonstrated that 38% of women showing no signs of infection harbored *Mobiluncus* spp. They also showed that *Mobiluncus mulieris* predominates in the vaginas of healthy women (*Mobiluncus curtisii* was rarely detected). Hallén et al. (1987, 1988) reported the isolation of *Mobiluncus* spp. from the rectums of women (21–54%) with *Mobiluncus*-associated BV, and have suggested that, like *Candida* spp., *Mobiluncus* spp. contaminate the vagina from the rectum, which would explain finding these organisms in healthy women

as well as those with other *Mobiluncus*-related infections. Holst (1990) isolated *Mobiluncus* spp. from rectal samples of healthy men, women, and children, and suggested that they could be part of the normal intestinal microbiota, probably occurring in low numbers. Because of the complex nature of this microbiota, isolation of *Mobiluncus* spp. from intestinal samples would therefore, be difficult. Consequently, molecular methods are more appropriate for detection of these organisms in vaginal and intestinal samples.

Role in pre-term delivery. In the past decade there has been an increased recognition that BV can contribute to pre-term delivery (Calderas et al., 1999; Hillier et al., 1995; Royce et al., 1999). In pregnant women showing pre-term labor signs and BV, Calderas et al. (1999) showed that ~7% had *Mobiluncus* spp. in their vaginal microbiota. However, no correlation between presence of *Mobiluncus* and pre-term birth has been shown. Micro-organisms associated with BV, and other genital infections, can ascend into the intra-amniotic cavity from the vagina and cervix and produce biochemical changes responsible for pre-term labor. Production of phospholipase C by *Bacteroides thetaiotaomicron*, *Gardnerella vaginalis*, *Prevotella bivia*, *Prevotella melaninogenica*, and group B streptococci has been demonstrated (McGregor et al., 1991). This enzyme has been shown to induce lysis and cellular rupture, producing loss of integrity in tissues and an increase in arachidonic acid production. These events are precursors to prostaglandin synthesis, which induces and maintains uterine contractions. However, the production of phospholipase C by *Mobiluncus* spp. has yet to be demonstrated. McGregor et al. (1994), however, did demonstrate that *Mobiluncus* spp. produce sialidase, an enzyme associated with periodontal infections. While *Mobiluncus* spp. may play a role in initiating pre-term delivery, it is more likely that the factors affecting pre-term birth are polymicrobial, and clearly more work is needed to elucidate the mechanisms by which the production of phospholipase C, sialidase, and other factors, are upregulated.

Presence in men. The presence of *Mobiluncus* spp. in male hosts has been documented by a number of authors; the general consensus is that these organisms are detectable only in a small number of men. Holst et al. (1984b) examined 309 men attending a clinic for sexually transmitted diseases and found that ten of them carried *Mobiluncus curtisii*. Four of the men found to be carrying this organism had urethritis. Vetere et al. (1987) reported the isolation of a strain of *Mobiluncus* from the seminal fluid of an infertile man. Hillier et al. (1990) obtained semen samples from 37 men attending a Special Infertility Clinic and found that 74 of the 188 isolates they obtained were anaerobic bacteria. *Mobiluncus* spp. were recovered from fewer than 10% of the specimens, with coagulase-negative streptococci, α-hemolytic streptococci, *Bacteroidaceae*, and *Gardnerella vaginalis* predominating. However, the clinical relevance, if any, of the presence of *Mobiluncus* spp. in seminal fluid was not elucidated. In a search for the possible reservoir and spread of four BV-associated micro-organisms (*Mobiluncus curtisii*, *Mobiluncus mulieris*, *Mycoplasma hominis*, and *Gardnerella vaginalis*), Holst (1990) examined the occurrence of these species in rectal, oral, and pharyngeal specimens from the male consorts of women with and without BV, homosexual men, and children. A total of 47 of 148 women with BV harbored both species, 45 only *Mobiluncus curtisii*, 20 only *Mobiluncus mulieris*, and 20 harbored neither species in their rectums. Only one healthy woman and one male partner of a healthy woman harbored *Mobiluncus curtisii*. Among the children studied, one boy and one girl harbored *Mobiluncus curtisii* in the rectum. Three girls harbored *Mobiluncus mulieris* in the rectum. *Mobiluncus* spp. were never recovered from the genital specimens of male consorts of healthy women. However, *Mobiluncus curtisii* and *Mobiluncus mulieris* were isolated from genital specimens of male partners of women with BV (*Mobiluncus curtisii* was isolated more frequently than *Mobiluncus mulieris*). None of the individuals examined in the study of Holst (1990) harbored *Mobiluncus* spp. in their throats or mouths.

Extragenital infections. There has also been increased interest in the incidence of extragenital infections caused by species of this genus. The isolation of members of the genus *Mobiluncus* from non-specific vaginal infections has been well documented. There have been a number of reports in recent years of members of the genus being isolated from extragenital infections. Extragenital infections associated with *Mobiluncus* were reported by Glupczynski et al. (1984) in four women. The strains were isolated over an 18-month period at Brugmann University Hospital, Belgium. Initially, the isolated unidentified organisms were thought to be related to *Wolinella succinogenes*. In the first reported case, a 29-year-old woman presented with a breast abscess. Her medical history indicated that she had had a benign cystadenoma removed from the opposite breast 6 months earlier, but symptoms for the breast abscess did not appear for another 5 months. Any link between the cyst removal and *Mobiluncus*-associated infection therefore seems unlikely. Direct puncture of the abscess using a needle yielded a yellowish, foul-smelling pus, suggesting the presence of anaerobic bacteria. Culture of the specimen produced "*unidentified curved anaerobic bacilli*" in association with *Bacteroides intermedius*, *Bacteroides urealyticus*, and *Peptococcus* spp.

The second case reported by Glupczynski et al. (1984) concerned a 60-year-old woman suffering from recurrent abdominal pain and bloody stools lasting 2 months. She also had a brownish discharge through the navel. The patient had a significant medical history, which included appendectomy, hysterectomy, and cholecystectomy within the previous 4 years. Laboratory findings for abdominal and rectal examinations were shown to be normal. However, bacteriological analysis of the umbilical discharge showed a mixed anaerobic flora comprising *Bacteroides intermedius*, *Wolinella succinogenes*, and anaerobic, comma-shaped rods.

The third case concerned a 41-year-old woman admitted to hospital with an exudative wound following a radical mastectomy. One month earlier the patient had undergone a total mastectomy of the left breast. On examination, a foul-smelling discharge was obtained from the lower part of the wound. Chloramphenicol powder was administered onto the wound, and total recovery was observed within 1 week. Laboratory examination of swabs taken from the wound showed the presence of *Bacteroides assacharolyticus*, *Peptostreptococcus anaerobius*, *Eubacterium* spp., and another unidentified anaerobic curved bacilli. Again, this organism was retrospectively identified as *Mobiluncus* spp.

Sturm and Sikkenk (1984) also reported the isolation of short anaerobic rods in pure culture from the discharge of a breast abscess in a 33-year-old woman. Although motile curved rods

were not isolated from the vagina of the patient, the infection was thought to be due to transfer of vaginal *Mobiluncus* to the breast area during sexual intercourse, or auto-infection via the hands. Sturm (1989) came to a similar conclusion to explain the presence of *Mobiluncus* spp., and other vagina-associated bacteria, in samples taken from breast abscesses. Weinbren et al. (1986) described the isolation of a *Mobiluncus* spp. from the non-puerperal breast abscess of a woman who had undergone a bilateral submammary excision 3 years previously. The organism was isolated in mixed culture with a *Bacteroides* spp., but the significance of the *Mobiluncus* strain in this infection is not known. Edmiston et al. (1989) also described the isolation of *Mobiluncus curtisii* (in combination with *Bacteroides bivius*, *Bacteroides capillosus*, *Bacteroides ureolyticus*, several *Peptostreptococcus* spp. and *Staphylococcus epidermidis*) from a breast abscess in a woman 5 months post-partum. The authors postulated that the trauma caused by childbirth 5 months previously may have precipitated the hematogenous seeding of the breast tissue.

The final case reported by Glupczynski et al. (1984) pertained to a 39-year-old alcoholic woman with a 1-week history of abdominal pain, fever, and jaundice. In the previous 6 months she had suffered an episode of hepatic encephalopathy. Blood cultures were taken, leading to the isolation of pure cultures of *Mobiluncus* spp. from two separate anaerobic blood bottles 9 d after they had been inoculated. In all four cases described by Glupczynski et al. (1984), none of the patients had symptoms or signs of genital tract infections. The clinical significance and source of infection were unclear for the first three cases, as the *Mobiluncus* spp. were isolated in mixed culture. In the final case, the authors suggested the colon as the likely portal of entry, as "*patients with liver cirrhosis show a high frequency of spontaneous bacteremia originating from the digestive tract*". However, this link is still tentative, as the isolation of *Mobiluncus* from the patient's stool specimen was not attempted.

Curtis (1913) isolated *Mobiluncus* spp. (in mixed culture) from a woman who suffered an infection following an instrumental abortion, and from a woman who had an infection that complicated labor at full-term. *Mobiluncus* spp. have also been isolated from an abdominal abscess of a woman with pelvic inflammatory disease (PID; cited in Fohn et al., 1988). A correlation has been found between presence of *Mobiluncus* spp. and "clue cells" in vaginal discharge and the incidence of PID after first-trimester abortions (Larsson et al., 1989); however, the role, if any, of *Mobiluncus* spp. in this disease is not known. Larsson et al. (1986) also described the identification of *Mobiluncus*-specific antibodies in serum samples from a woman with a post-operative infection (the woman had undergone a hysterectomy). Severe sepsis caused by *Mobiluncus curtisii* in a previously healthy 54-year-old woman has been documented (Hill et al., 1998). *Mobiluncus mulieris* has been isolated from an abdominal abscess in a 62-year-old woman (Mayer et al., 1994).

Hosts other than humans. The prevalence of *Mobiluncus* spp. in hosts other than man has not been investigated thoroughly. In a study of vaginal samples from 37 rhesus macaques, Doyle et al. (1991) observed the presence of curved Gram-stain-negative rods in Gram stains of vaginal smears. The macaques (age, 4–22 years old) had no history of vaginitis or septic abortion. Samples were taken in the middle of the menstrual cycle prior to bleeding. Using tests such as catalase production, oxidase production, motility, and GLC analysis of acid end products, the rods were characterized as *Mobiluncus curtisii* subsp. *curtisii* (found in 46% of all the animals tested). Half of the animals that carried *Mobiluncus curtisii* subsp. *curtisii* also harbored *Gardnerella*-like organisms. This is the first and only case describing the isolation of *Mobiluncus* spp. in hosts other than man. Notably, the *Mobiluncus curtisii* subsp. *curtisii* strains were isolated from healthy animals. To date, no environmental sources of members of the genus *Mobiluncus* have been reported.

Pathogenicity. While the presence of *Mobiluncus* spp. in vaginal fluids is associated with BV, the etiological role of these organisms in this condition is unknown and difficult to assess. *Mobiluncus* spp. have never been recovered in pure culture from vaginal discharges, and they have been identified in healthy and BV-affected women (Schaal et al., 2005). In addition, there has been no demonstration of a difference in the severity of BV symptoms when *Mobiluncus* spp. are present in or absent from the vaginal flora (Jones et al., 1985). Taking these factors into account, one cannot exclude the pathogenic potential of these organisms, as these observations are true for other anaerobic species that predominantly or exclusively occur in synergistic mixed infections (Schaal et al., 2005). It is interesting to note, however, that *Mobiluncus curtisii* appears to be more prevalent than *Mobiluncus mulieris* in BV patients (Moi et al., 1991; Schwebke and Lawing, 2001).

Potential virulence factors. Several studies have shown that *Mobiluncus* spp. can attach to vaginal epithelial cells. Fredricsson et al. (1984) showed that, compared to *Gardnerella vaginalis*, *Mobiluncus* spp. had a greater degree of adherence to vaginal epithelial cells. Moi et al. (1984a) examined the influence of pH on the adhesion of *Mobiluncus* spp. to vaginal epithelial cells obtained from healthy women. They found that adherence of *Mobiluncus* spp. increased as the pH increased, with *Mobiluncus mulieris* adhering significantly better than *Mobiluncus curtisii* at pH 7.5 when compared with pH 4.0. They also demonstrated that "clue cells" seen in wet mounts from vaginal discharge of women with BV were very similar to *Mobiluncus*-covered vaginal epithelial cells in *in vitro* tests. Catalanotti et al. (1994) also demonstrated the adhesion of *Mobiluncus curtisii* to vaginal epithelial cells at pH 5.4, the normal vaginal pH on the 22nd day of the menstrual cycle, but showed that it adhered less well at 4.8 (the pH on the 24th day of the menstrual cycle) and 4.4 (the pH during peak ovulatory phases). De Boer and Plantema (1988) showed that *Mobiluncus* spp. attached both directly to epithelial cell surfaces and at various distances from them. They concluded that, after initial attachment, *Mobiluncus* spp. can grow at the epithelial surface in sessile microcolonies. Also conspicuous was the ability of the curved bacilli to attach to the epithelial cells via their cell tips. However, *in situ*, no specialized bacterial cell surface structures were seen that might explain this polar attachment. Using ruthenium red staining, they also demonstrated the presence of precipitated glycocalyx material on both the flagellae and surfaces of the bacilli. This led the authors to postulate that the bacilli were enclosed in a very hydrated matrix of exopolysaccharides. In fact, the production of a glycocalyx was demonstrated *in vitro* for *Mobiluncus curtisii* subsp. *curtisii* and *Mobiluncus mulieris* (De Boer and Plantema, 1988). Using luminol-enhanced chemiluminescence, *Mobiluncus curtisii* was shown to induce a significantly less pronounced oxidative metabolism of polymorphonuclear leukocytes than

Mobiluncus mulieris, implying that the former species is able to escape phagocytosis more easily (Schaal et al., 2006). This observation led Schaal et al. (2006) to postulate that the curved rods seen inside phagocytic vesicles of vaginal polymorphonuclear leukocytes by De Boer and Plantema (1988) were *Mobiluncus mulieris* rather than *Mobiluncus curtisii*.

Eleven strains of *Mobiluncus curtisii* and four strains of *Mobiluncus mulieris* were shown to produce a cytotoxin after growth in three different liquid media (Taylor-Robinson et al., 1993). The cytotoxin, present in supernatant fluids after centrifugation, was active against Vero cells and four other cell lines tested, producing a marked cytopathic effect within 72 h. Of the supernatant fluids from eight *Mobiluncus curtisii* strains and two *Mobiluncus mulieris* strains tested, all caused loss of ciliary vigor of bovine oviduct organ cultures. This process was usually complete after 60 h and caused raggedness of the epithelial cell border and loss of cilia. The toxin was extracellular, relatively heat-stable, inactivated under extremes of pH, and not found in colonies isolated from solid medium nor in centrifuged deposits from organisms grown in broth culture. However, the demonstration of the ability of *Mobiluncus* spp. to produce toxin suggests that these organisms could have a role in BV. The findings of Menolascina et al. (1999) corroborated the results of Taylor-Robinson et al. (1993), since filtered supernatants of 11 of 12 *Mobiluncus* strains tested produced a cytopathic effect on HeLa cells at dilutions of up to 1:16.

Ison et al. (1989) presented preliminary data showing that one of their mAbs (180.1) inhibited attachment of *Mobiluncus curtisii* cells to exfoliated vaginal epithelial cells *in vitro*. They postulated that this was a situation analogous to that observed in *Neisseria gonorrhoeae* with regard to its PII family of proteins: these proteins enhance the ability of gonococci to adhere to vaginal epithelial cells. Therefore, Ison et al. (1989) may have detected an outer-membrane protein in *Mobiluncus curtisii* that had a role in colonization; however, this hypothesis requires support through more-detailed studies.

Clearly, more work is required to elucidate the adhesin(s) present in the cell wall of *Mobiluncus* spp. and to characterize the toxin(s).

Enrichment and isolation procedures

Members of the genus *Mobiluncus* are fastidious anaerobic organisms and, as such, require enriched media to grow. Their isolation from vaginal samples has proven difficult over the years as they are slow growing and are rapidly overgrown by co-habiting organisms, such as *Bacteroides* spp., *Gardnerella vaginalis*, *Lactobacillus* spp., and *Streptococcus* spp. (Hammann et al., 1984; Hernández et al., 1994; Smith and Moore, 1988). *Mobiluncus* spp. are easily grown on non-selective, nutrient-rich medium once they have been isolated from the other abundant anaerobic micro-organisms associated with BV. The process of isolating *Mobiluncus* spp. in pure culture can be lengthy, taking weeks of subculturing before pure cultures are obtained. For this reason, a number of different selective media have been designed over the years, with a view to improving the yield of *Mobiluncus* strains from vaginal samples. Most of these media rely on the addition of animal blood or serum to provide the enriched environment that the micro-organisms require. Recovery of *Mobiluncus* spp. from vaginal samples can also be enhanced by the use of antibiotics/inhibitors in media, and the use of selective techniques. Table 16 details some of the selective agars that have been used for the isolation of *Mobiluncus* spp. from human vaginal samples.

TABLE 16. Examples of agars used to isolate and culture *Mobiluncus* strains

Agar used[a]	Reference(s)
Blood agar	Curtis (1913); Moore (1954)
Colistin/nalidixic acid agar + 2.5% horse serum, nalidixic acid (5 µg/ml)	Durieux and Dublanchet (1980); Holst et al. (1982)
Enriched tryptone soya agar	Fontaine et al. (1982)
Brain heart infusion agar + 5% sheep blood, hemin (5 µg/ml), 0.5% yeast extract, menadione (0.5 µg/ml)	Hjelm et al. (1982)
Columbia blood agar + hemin (0.5 µg/ml), vitamin K_1 (0.5 µg/ml)	Holst et al. (1982)
Columbia blood agar	Phillips and Taylor (1982)
Oxoid DST agar + 5% defibrinated horse blood, 1% hemin, 0.2% vitamin K, 0.5% yeast extract	Sprott et al. (1982)
Columbia agar + 5% human blood, 0.2% vitamin K	Sprott et al. (1983)
Columbia agar + tinidazole (1 mg) + colistin (10 mg) + nalidixic acid (15 mg)	Holst et al. (1984a)
Brain heart infusion agar + 5% horse blood	Vetere et al. (1987)
Brucella agar + 5% horse blood	Vetere et al. (1987)
Wilkins–Chalgren agar + 5% horse blood	Vetere et al. (1987)
SA agar. Columbia blood agar + laked rabbit or sheep blood (16 ml) + rabbit serum (20 ml)	Smith and Moore (1988)
Rlk agar. Columbia CNA agar + yeast extract (6 g) + peptone (20 g)	Smith and Moore (1988)
Mobi agar. Columbia broth + Bacto agar + cysteine hydrochloride (0.4 g) + soluble starch (10 g) + resazurin solution (4 ml of 11 mg/44 ml solution) + colistin methane sulfonate (10 mg) + nalidixic acid (15 mg)	Spiegel (1992)
Horse blood agar	Gatti (2000)
Schaedler blood agar 107 (with nalidixic acid, 1 µg/ml)	Calderas et al. (1999)
Schaedler blood agar 108 (with nalidixic acid, 1 µg/ml, and vancomycin, 2.5 µg/ml)	Calderas et al. (1999)

[a]All formulations are for the preparation of 1 liter of medium. All % values are v/v percents, except for the % of yeast extract, which is a w/v percent.

In the past, the blood from a wide variety of mammals has been used in the preparation of these selective media: e.g., human (Curtis, 1913; Hammann et al., 1984; Hjelm et al., 1984; Moore, 1954; Sprott et al., 1983), goat (Curtis, 1913), sheep (Curtis, 1913; Hammann et al., 1984; Moore, 1954; Smith and Moore, 1988), rabbit (Smith and Moore, 1988), guinea pig (Moore, 1954) and horse (Fox and Phillips, 1984; Moore, 1954; Sprott et al., 1982). Although a wide variety of blood types has been used, it is generally recognized that the source of the blood used in the medium does not greatly affect the growth of

strains of *Mobiluncus* spp. (although hemolytic activity is always observed on rabbit blood; Thomason et al., 1984). A wide range of blood concentrations (4–20%) have been used for the cultivation of *Mobiluncus* spp. from vaginal samples, although blood concentration above 4% has no effect on the growth or hemolytic activity of strains of *Mobiluncus* spp. (Holst et al., 1982). In addition, no appreciable difference in colony size is noted when laked blood is used as a substitute to whole blood (Thomason et al., 1984). The addition of serum to solid medium appears to stimulate the growth of *Mobiluncus* strains. Thomason et al. (1984) noted that, although serum improves the growth of *Mobiluncus* spp., only the addition of fetal calf serum to the medium increases the size of colonies. They suggested the use of a colistin/nalidixic acid (CNA)-based agar containing 5% rabbit blood and 7% fetal calf serum to maximize the growth of *Mobiluncus* strains.

It is questionable whether both colistin and nalidixic acid should be added to the selective agars described, as no synergistic effect has been demonstrated between them (Holst et al., 1984a). Also the usefulness of CNA-based selective agars to enrich for *Mobiluncus* strains is somewhat controversial, as Hammann et al. (1984) have suggested that the CNA agar of Durieux and Dublanchet (1980) regularly allowed good growth of *Bacteroides* spp., *Gardnerella vaginalis*, lactobacilli, and anaerobic cocci. Other inhibitory agents added to solid media have included trimethoprim plus polymyxin B, tinidazole plus colistin or nalidixic acid, tinidazole (to which some strains of *Mobiluncus mulieris* are susceptible at concentrations greater than 4 μg/ml), and Nile blue A (Spiegel, 1992).

Growth of *Mobiluncus* spp. in broth culture is relatively poor. However, Vetere et al. (1987) showed that strains grew best in broth cultures when the pH of the medium was 6–8 (sparse growth was observed at pH <6). Numerous broths have been tested for their suitability as growth media, including peptone/yeast, peptone/yeast/glucose, thioglycollate and Mueller–Hinton (Holst et al., 1982), Todd–Hewitt broth and Robertson's cooked meat medium (with and without hemin, sodium fumarate, sodium formate, and vitamin K; Sprott et al., 1983), and tryptone soya and brain heart infusion (Fontaine et al., 1982). Curtis (1913) was unable to culture *Mobiluncus* spp. in broth culture, but this was likely due to the limitations on anaerobic culturing at the beginning of the twentieth century. Sprott et al. (1983) reported that they were unable to grow *Mobiluncus* spp. consistently well in liquid culture, and that the addition of vitamin K to a medium had no effect on the level of growth. There are conflicting reports regarding the growth benefits of serum addition to broths (Holst et al., 1982; Taylor-Robinson and Taylor-Robinson, 2002; Vetere et al., 1987). Several authors have reported that fumarate/formate solution has no effect on the growth of *Mobiluncus* spp., in either solid or liquid medium (Hjelm et al., 1982; Spiegel and Roberts, 1984a; Sprott et al., 1983; Vetere et al., 1987). However, Holst et al. (1982) observed that the addition of 0.3% fumarate/formate slightly improved growth in chopped meat, peptone/yeast, and peptone/yeast/glucose broths. Holst et al. (1982) also observed that the addition of 3% horse serum to thioglycollate broth led to the development of heavy, turbid, granular growth. Spiegel and Roberts (1984a) found that growth in peptone/yeast broth was improved by the addition of maltose and glucose (carbohydrates found in the human vagina). Moore (1954) obtained best growth of the species in Brewer's thioglycollate broth enriched with 10% serum. Taylor-Robinson and Taylor-Robinson (2002) evaluated the suitability of nine different broths for growth of *Mobiluncus* strains. They concluded that a few commercial liquid media were excellent for growth, and even suggested that Columbia blood broth or peptone starch glucose broth would suffice if supplemented with horse serum (10%). A bacterial strain was selected that was known to multiply to high numbers (as some strains, whatever the medium, consistently reached maximal titers greater than others), and an initial inoculum of 10^5–10^6 organisms per milliliter was used.

Two different enrichment techniques have been suggested for improving the yield of *Mobiluncus* spp. from vaginal samples. The first method involves pre-treatment of the vaginal sample with alkali (Påhlson and Forsum, 1985; Påhlson et al., 1986b) and is based on the knowledge that *Mobiluncus* spp. are more resistant to alkaline solutions than most of the other bacterial species present in vaginal discharge. Påhlson and colleagues suggested that the high content of extractable lipids (approx. 0.7% wet weight in packed cells, compared with 0.3 and 0.4% for *Escherichia coli* and *Bacteroides fragilis*, respectively) may account for the success of this technique. Samples of vaginal discharge were diluted in buffer (pH 12.0) for 10 min, leading to a tenfold drop in the recovery of organisms other than members of the genus *Mobiluncus*. Treatments at pH 12.3 and 12.6 for 5–10 min were also shown to be effective, but the recovery of *Mobiluncus* spp. after 10 min was drastically reduced or not possible due to death of the bacteria, respectively. Within the genus *Mobiluncus*, species and strains differ in their tolerance to alkali, with *Mobiluncus curtisii* strains having prolonged survival times in high-pH buffers. These authors also pre-cultured samples in an enrichment broth, such as brain heart infusion broth supplemented with 2% inactivated serum and filter-sterilized maltose solution (1% final concentration) and pH 12.0. After 2 d growth, the samples were subcultured onto plates, and pure cultures of *Mobiluncus* spp. were available within 1–2 weeks.

The second method involves cold enrichment at 4 or 5°C (Smith and Moore, 1988). These authors used Rlk agar, SA agar, Brucella blood agar, and Mobi agar (Table 16). Storage of pure cultures of *Mobiluncus curtisii* and *Mobiluncus mulieris* for 1, 5, and 25 h in anaerobic storage medium under cold enrichment conditions prior to inoculation onto each of the four different agars did not enhance the recovery of *Mobiluncus* spp.; in fact, recovery of these organisms decreased (10–40 c.f.u. to 1–9 c.f.u.) on Brucella blood agar when compared with cultures kept at room temperature (for 24 h) prior to inoculation. In mixed cultures containing *Bacteroides* spp., *Gardnerella vaginalis*, *Peptostreptococcus* spp., *Staphylococcus aureus*, *Mobiluncus mulieris*, *Mobiluncus curtisii* subsp. *curtisii*, and *Mobiluncus curtisii* subsp. *holmesii*, recovery of *Mobiluncus* spp. increased after cold enrichment on Rlk and SA media (1–9 c.f.u. after 1 h at room temperature to 10–40 c.f.u. after 1, 5, and 24 h at cold enrichment). Growth of *Mobiluncus* spp. at room and cold temperatures was poor on Brucella blood agar (0 to 1–9 c.f.u.) and prone to overgrowth by other organisms on Mobi agar. The most abundant growth of *Mobiluncus* spp. was obtained on SA medium. However, Smith and Moore (1988) recommend the use of both media in clinical isolation of *Mobiluncus* spp., since differences in chemical composition (i.e., yeast extract, additional peptone and laked horse blood versus serum and laked

blood) between media allows the growth of different organisms. Hence, overgrowth does not usually occur in both media. Use of this method allows *Mobiluncus* spp. to grow at rates similar to those of other anaerobic members of the vaginal flora, and allows their isolation even when they are present in very low numbers. This method is effective in the isolation of *Mobiluncus* spp. from mixed populations according to Smith and Moore (1988) because cold enrichment slows the metabolism of competing flora present during BV to a rate that allows *Mobiluncus* spp. to compete successfully with them; cold temperature, in combination with the selective media, provides *Mobiluncus* spp. with the advantage they need to survive among the less-fastidious, rapidly multiplying mixed flora.

Maintenance of *Mobiluncus* strains is also relatively easy. A number of suitable methods have been suggested for storing strains of *Mobiluncus*. These include traditional skimmed-milk/freeze-drying treatments before storage at 10°C or at −70°C. Hammann et al. (1984) suggested maintenance in Rosenow broth (48 h, 37°C) under sterile paraffin wax or under CO_2 and black stoppers and then freezing at −20 or −70°C. Samples were stored by Spiegel and Roberts (1984a) at −20 or −70°C in double-strength skimmed milk and used within five passages of recovery from frozen stocks. Samples stored at −70°C in 50% fetal calf serum plus 50% trypticase soy broth (Fohn et al., 1988) were still viable two years after freezing.

Differentiation of the genus *Mobiluncus* from other genera

Characteristics useful for differentiating *Mobiluncus* spp. from related genera can be found in Table 17.

Taxonomic comments

Members of the genus *Mobiluncus* have been known by different names: "Vibrion de Curtis", "*Vibrio mulieris*" (Prévot, 1940), and "vibrions succinoproducteurs" (Durieux and Dublanchet, 1980). However, after a number of studies on strains of curved rods from the vagina (Blackwell et al., 1983; Fontaine et al., 1982; Hammann et al., 1984; Hjelm et al., 1982; Holst et al., 1982; Phillips and Taylor, 1982; Skarin and Mardh, 1982; Spiegel and Roberts, 1984a; Sprott et al., 1982, 1983; Taylor and Owen, 1984) these organisms were shown to differ from organisms of the genera recognized at that time.

On the basis of these data, studies were carried out to characterize the relationship of these organisms. Two studies were undertaken concurrently, leading to descriptions of the genera *Falcivibrio* (Hammann et al., 1984) and *Mobiluncus* (Spiegel and Roberts, 1984a). Although the name *Falcivibrio* was published first, it was not validated in the *International Journal of Systematic Bacteriology* first; therefore, the name *Mobiluncus* takes precedence. However, the genus name *Falcivibrio* has not been removed from the approved list of bacterial names. Spiegel and Roberts (1984a) tentatively placed the genus *Mobiluncus* in the family *Bacteroidaceae*; however, a later 16S rRNA gene-based study by Lassnig et al. (1989) demonstrated that the genus seemingly belongs to the order *Actinomycetaceae*, family *Actinomycetaceae*.

Currently, two species of the genus are recognized: *Mobiluncus curtisii* (*Falcivibrio vaginalis*) and *Mobiluncus mulieris* (*Falcivibrio grandis*). *Mobiluncus mulieris* is negative for hippurate hydrolysis, arginine dihydrolase activity, and β-galactosidase activity, while *Mobiluncus curtisii* is positive for these traits. SDS-PAGE, DNA–DNA hybridization, serological, and 16S rRNA gene sequence studies have supported the delineation of the two species (Baron et al., 1984; Hoyles et al., 2004; Moi and Danielson, 1984; Spiegel and Roberts, 1984a; Taylor and Owen, 1984; Tiveljung et al., 1996). *Mobiluncus curtisii* was divided into two subspecies, *Mobiluncus curtisii* subsp. *curtisii* (nitrate-negative and able to migrate through soft agar) and *Mobiluncus curtisii* subsp. *holmesii* (nitrate-positive and unable to migrate through soft agar) (Spiegel and Roberts, 1984a), but evidence for the need of subspecies is conflicting. DNA–DNA hybridization studies on "short curved rod" (*Mobiluncus curtisii*) strains showed that strains comprising *Mobiluncus curtisii* may represent several species (Christiansen et al., 1984); however, further biochemical and serological studies were required for delineation of this species. The case for subspecies was supported by the absence of surface antigens of *Mobiluncus curtisii* subsp. *curtisii* from *Mobiluncus curtisii* subsp. *holmesii* (Fohn et al., 1988). However, Påhlson et al. (1986a) were able to distinguish between *Mobiluncus curtisii* and *Mobiluncus mulieris* (and atypical) strains but not able to split the *Mobiluncus curtisii* strains into the two subspecies using mAbs. Hoyles et al. (2004) found that the type strains of the two subspecies were unable to reduce nitrate or pit agar. Other examples of the phenotypic complexity among *Mobiluncus* spp., particularly within *Mobiluncus curtisii* strains, are available within the literature (Carlone et al., 1986; Garlind et al., 1989; Skarin, 1986; Vetere et al., 1987). The identification of atypical strains has also clouded the issue of speciation within the genus *Mobiluncus* (Christiansen et al., 1984; Påhlson et al., 1986a; Vetere et al., 1987).

Hoyles et al. (2004) also found that the system used to biochemically characterize strains produced varying results. While useful for characterizing *Mobiluncus* spp., biochemical tests produce results that are highly method-dependent. This may be especially true for the detection of weak or very weak acid production from carbohydrates, which may also be influenced by size and viability of inoculum, or the techniques used for obtaining anaerobic growth conditions (Schaal et al., 2005). Clearly, fermentation pattern is not a reliable criterion for differentiation of *Mobiluncus* spp. (Vetere et al., 1987). Spiegel (1992) is of the opinion that differences between the subspecies are due mainly to normal strain variation and differences in media and methods. In contrast, Hoyles et al. (2004) think that *Mobiluncus curtisii* strains should be considered a single but complex entity that cannot be separated into distinct subspecies on the basis of physiological markers alone. The taxonomy of the genus *Mobiluncus* is still unclear because not all strains fulfil the criteria proposed for the two species (Vetere et al., 1987). However, molecular tools provide the opportunity to determine the true taxonomy of this interesting group of bacteria.

Differentiation of the species of the genus *Mobiluncus*

The traits used to differentiate *Mobiluncus curtisii* and *Mobiluncus mulieris* are shown in Table 18. Strains can be allocated to species using 16S rRNA gene sequencing. *Mobiluncus curtisii* and *Mobiluncus mulieris* can be separated on the basis of differences

TABLE 17. Characteristics useful for distinguishing *Mobiluncus* from related genera[a,b]

Genus	*Actinomyces*	*Arcanobacterium*	*Actinobaculum*	*Varibaculum*	*Mobiluncus*
End products of glucose fermentation	Acetic, lactic, and succinic (major/minor) acids[c]	Acetic (major/minor), lactic, and succinic (minor) acids	Acetic and succinic acids	Lactic, acetic (minor), and succinic acids	Acetic, lactic (minor/absent), and succinic acids
DNA G+C content (mol%)	57.5–71	48.4–66	55–57	51.7	49–54
Aerobic growth	v	+	v	–	–
Motile	–	–	–	–	+
Filamentous microcolonies	+	–	–	–	–
Nitrate reduction	v	v	–	v	v
Catalase	v	v	–	–	–
Habitat	Mucosal surfaces of humans and animals[d]	Presumed to be commensals of mucous surfaces of warm-blooded animals	Unknown, but probably genital or urinary tract[e]	Not known, but isolated from human clinical sources[f]	Human vagina and rectum; vagina of rhesus macaque

[a]Symbols and abbreviations: v, variability among species and strains of the genus; –, negative; +, positive.

[b]All data are from Bowden (1998), Buchanan et al. (1984), Cato et al. (1984), Collins and Cummins (1986a), Collins et al. (1982b, 1993), Dent and Williams (1984b, 1984c, 1986), Funke et al. (1994, 1995, 1997a), Hall et al. (2003e), Hammann et al. (1984), Johnson et al. (1990), Lawson et al. (1997, 2001b), Lehnen et al. (2006), Pascual et al. (1995a).

[c]Formic and pyruvic acids are sometimes produced by strains of *Actinomyces georgiae*, *Actinomyces gerencseriae*, and *Actinomyces meyeri*. Lactic and pyruvic acids only detected in *Actinomyces georgiae* cultures when incubated aerobically (Johnson et al., 1990).

[d]*Actinomyces radingae* and *Actinomyces turicensis* strains have been isolated from human feces (L. Hoyles, unpublished data).

[e]An *Actinobaculum schaalii*-like bacterium has been isolated from human feces (L. Hoyles, unpublished data).

[f]*Varibaculum cambriense*-like strains have been isolated from human feces (L. Hoyles, unpublished data).

TABLE 18. Tests useful for differentiating *Mobiluncus curtisii* and *Mobiluncus mulieris*[a]

Biochemical test	*M. curtisii* ($n = 12$)	*M. mulieris* ($n = 10$)
Arginine dihydrolase	+	−
β-Galactosidase	$+^-$	−
β-Galacturonidase	−/+	−
α-Galactosidase	$+^-$	−
α-Fucosidase	−	−/+
Pyrazinamidase	−/+	−
Tyrosine arylamidase	−/w	+
Alanine arylamidase	−/w	+
α-Glucosidase	−/+	+
Serine arylamidase	−	−/w
Leucine arylamidase	−/+	+
Hippurate hydrolysis	$+^-$	−
Maltose fermentation	$-^+$	+
Sucrose fermentation	−	$+^-$
Ribose fermentation	−	$+^-$
Trehalose fermentation	−	+
Nitrate reduction	$-^+$	−
Leucyl glycine arylamidase	+	−/w

Symbols and abbreviations: +, All or ≥95% strains positive; −, all or ≥95% strains negative; −/+, variable reaction; $+^-$, majority of strains positive, but some negative; −/w, strains negative or weak; $-^w$, majority of strains negative, but some weak; $-^+$, majority of strains negative, but some positive.

[a]Results presented here are representative for four different API strips (Hoyles et al., 2004).

in the V3 (GATGGTTCCAGAGATGGGCCAGCCTT→GA CA-T GCCAGAGATGG TGTGGCCTT) and V4 (AGCG-GTTCGGCCGGGG→AGC ACGTT ATG GTGGGG) regions (Hoyles et al., 2004; Tiveljung et al., 1995, 1996) of their 16S rRNA gene sequences. There appears to be sequence heterogeneity among strains of *Mobiluncus curtisii*, while none is observed among *Mobiluncus mulieris* strains (Hoyles et al., 2004). SDS-PAGE has been used by a number of different groups to split *Mobiluncus* strains into the two species (Baron et al., 1984; Drouet et al., 1991; Hoyles et al., 2004; Taylor and Owen, 1984; Vetere et al., 1987). Intraspecies levels of association suggest that members of the two species represent several distinct groups, as correlations within strains designated *Mobiluncus curtisii* were as low as ~55%, and those within strains of *Mobiluncus mulieris* were as low as ~65% (Hoyles et al., 2004). High correlation values (~84%) for SDS-PAGE profiles and the corresponding biochemical profiles of the same *Mobiluncus curtisii* strains did not correlate. This was also observed for *Mobiluncus mulieris* strains (even though some pairs showed correlation values of >90%). SDS-PAGE analysis is a useful tool for differentiating between the two species of *Mobiluncus* and in intraspecies typing; however, it is of little use in subspecies delineation. Although analysis of whole-cell proteins allows intraspecies clustering of strains (Drouet et al., 1991), these clusters are meaningless because the biochemical properties of the strains are complex.

Preliminary work using pulsed-field gel electrophoresis has demonstrated that *Mobiluncus curtisii* and *Mobiluncus mulieris* can be separated using the enzyme *Spe*I (Hoyles et al., 2004). Although further work is required to optimize conditions for isolation of high-quality DNA from *Mobiluncus mulieris* strains, use of *Spe*I demonstrated strain heterogeneity among *Mobiluncus curtisii* isolates, supporting the conclusion of heterogeneity within this species drawn by researchers using SDS-PAGE.

Ampicillin, cefotoxin, cephalothin, and moxalactam are more active against *Mobiluncus mulieris* strains than *Mobiluncus curtisii*, while colistin is more active against *Mobiluncus curtisii* than *Mobiluncus mulieris* (Spiegel, 1987). *Mobiluncus mulieris* is more susceptible than *Mobiluncus curtisii* to alizarin red, Evans blue, and sodium fluoride (Spiegel, 1987). As discussed in the Antibodies section of this chapter, *Mobiluncus curtisii* and *Mobiluncus mulieris* can be distinguished by using species-specific mAbs.

List of species of the genus *Mobiluncus*

1. **Mobiluncus curtisii** Spiegel and Roberts 1984a, 181[VP] emend. Hoyles, Collins, Falsen, Nikolaitchouk and McCartney 2004 (Later heterotypic synonym: *Falcivibrio vaginalis* Hammann, Kronibus, Viebahn and Brandis 1984.)

   cur.ti′si.i. N.L. gen. masc. n. *curtisii* of Curtis, named after A.H. Curtis, who isolated the first strain.

   The species description is based on those of Spiegel and Roberts (1984a), Hammann et al. (1984), and Hoyles et al. (2004). Members of the species have the characteristics of the genus. Cells are anaerobic, Gram-stain-variable or Gram-stain-negative, slightly curved, non-spore-forming, rod-shaped (0.4–0.6 µm wide and 2–3 µm long, with ends slightly rounded and often pointed), and occur singly or in pairs. Motile by means of multiple subterminal flagella. Colonies on chocolate agar are cream to light-brown in color, convex, smooth, and entire after 5 d anaerobic incubation at 37°C, reaching 2–4 mm in diameter. Cultures are more turbid in peptone/yeast extract broth supplemented with rabbit serum and glycogen or maltose than in peptone/yeast extract broth supplemented with glucose and rabbit serum or rabbit serum alone. Growth is stimulated by arginine, and by fumarate, which is reduced to succinate. Traces of formate are formed from malate. Ammonia, citrulline, and ornithine are produced from arginine. Positive for arginine dihydrolase and histidine arylamidase (except for CCUG 21018[T]); negative for α-fucosidase and serine arylamidase activity. Variable activity for β-galacturonidase (RapID 32Strep system), α-galactosidase (positive API ZYM, variable API CORYNE), α-glucosidase (positive API 32AN and API ZYM, variable API CORYNE), β-galactosidase (API ZYM), pyrazinamidase (API CORYNE), tyrosine arylamidase (API 32AN), alanine arylamidase (API 32AN), phosphoaminidase (API ZYM), and leucine arylamidase (API ZYM). Negative for serine arylamidase activity. Does not produce acid from cyclodextrin, glucogen, melezitose, melibiose (except strain CCUG 22338), pullulan, ribose, sucrose, tagatose, or trehalose. Using the API CORYNE system, production of acid from glucose, lactose, maltose, and D-xylose is variable;

negative for acid production from maltose using the RapID 32Strep system; variable acid production from mannose and raffinose using the API 32AN system. Fermentation products from glycogen include succinate, trace amounts of fumarate, and moderate amounts of acetate. Products in peptone/yeast extract/glucose broth are acetic, lactic, and succinic acids; the same products are formed in peptone/yeast extract broth but in smaller amounts. Minor amounts of gas formed under a paraffin wax seal over a broth culture. Most strains hydrolyze hippurate (strains CCUG 44166B and CCUG 14425 do not). Esculin is generally not hydrolyzed (CCUG 22339 and CCUG 44116B positive). Starch and hippurate are hydrolyzed in the absence of serum. Reduction of nitrate to nitrite is variable. May "pit" agar (1.5%) after 5 d anaerobic incubation at 37°C. May migrate through soft (0.25%) agar. A weak CAMP reaction is produced on Brucella agar supplemented with 5% sheep blood when *Staphylococcus aureus* ATCC 25923 is used. Associated with BV, but role in pathogenicity is not known.

holme′si.i. N.L. gen. masc. n. *holmesii* of Holmes, named after K.K. Holmes, a researcher of sexually transmitted diseases.

Strains have the characteristics of the genus and those given for *Mobiluncus curtisii.*

DNA G+C content (mol%): 51–52 (T_m; Spiegel and Roberts, 1984a); 53–54 (T_m; Hammann et al., 1984).

Type strain: BV376-6, ATCC 35242, CCUG 17762, LMG 7786, NCTC 11657.

Sequence accession no. (16S rRNA gene): AJ427624.

2. **Mobiluncus mulieris** Spiegel and Roberts 1984a, 181[VP] (Later heterotypic synonym: *Falcivibrio grandis* Hammann, Kronibus, Viebahn and Brandis 1984.)

mu.li′e.ris. L. gen. n. *mulieris* of a woman.

Species description is based on those of Spiegel and Roberts (1984a), Hammann et al. (1984), and Hoyles et al. (2004). Members of the species have the characteristics of the genus. Cells are anaerobic, Gram-stain-variable or Gram-stain-negative, curved, non-spore-forming, rod-shaped, and occur singly, sometimes in pairs (then S- or U-shaped). Motile by means of multiple subterminal flagella. Cells are 0.4–0.6 μm wide and 2.5–5 μm long, and are usually thicker in the middle, with tapering ends. Colonies on chocolate agar are light-brown to brown in color, convex, smooth, and entire after 5 d anaerobic incubation at 37°C, reaching 2–4 mm in diameter. Growth is stimulated by fumarate, which is reduced to succinate and partially oxidized to malate. Cultures are more turbid in peptone/yeast extract broth supplemented with rabbit serum and glycogen or maltose than in peptone/yeast extract broth supplemented with rabbit serum alone. Growth is not stimulated by arginine. Citrulline, ornithine, and ammonia are not produced from arginine. Positive for alanine arylamidase, ester lipase (C8) (CCUG 17992 and 30101 weak-positive; API ZYM), α-glucosidase, and tyrosine arylamidase activity. Negative for arginine dihydrolase, β-galacturonidase, α-galactosidase, β-galactosidase, β-glucosidase, pyrazinamidase, and phosphoamidase (CCUG 20071^T weak-positive; API ZYM) activity. Negative to weak activity for esterase (C4) (API ZYM) and leucyl glycine arylamidase, glycine arylamidase, histidine arylamidase, and serine arylamidase (API 32AN). Variable activity for α-fucosidase. Produces acid from glucose (except for CCUG 30101, which is negative for this trait; API CORYNE), maltose, and trehalose. Does not produce acid from lactose. Variable acid production from ribose and sucrose using the RapID 32Strep and API CORYNE systems; variable acid production from melezitose, pullulan, and tagatose (RapID 32Strep), glucogen and D-xylose (API CORYNE), and mannose (API 32AN). Weak to negative acid production from cyclodextrin and raffinose. Fermentation products from glycogen include acetate, succinate, and trace amounts of fumarate; some strains produce trace amounts of oxaloacetate, pyruvate, and/or lactate. Products in peptone/yeast extract/glucose broth are acetic, lactic, and succinic acids; the same products are formed in peptone/yeast extract broth but in smaller amounts. Traces of gas formed under a paraffin wax seal over a broth culture. Esculin and hippurate are not hydrolyzed. Starch is hydrolyzed in the absence of serum. May "pit" agar after 5 d anaerobic incubation at 37°C. May migrate through soft (0.25%) agar. Nitrate is not reduced to nitrite. A strong CAMP reaction is produced on Brucella agar supplemented with 5% sheep blood when *Staphylococcus aureus* ATCC 25923 is used. Associated with BV, but role in pathogenicity is not known.

Source: human vagina.

DNA G+C content (mol%): 49–50 (T_m; Spiegel and Roberts, 1984a); 50–53 (T_m; Hammann et al., 1984).

Type strain: SV17J, ATCC 35243, CCUG 20071, LMG 7787, NCTC 11658.

Sequence accession no. (16S rRNA gene): AJ427625.

Genus V. **Varibaculum** Hall, Collins, Lawson, Hutson, Falsen, Inganas and Duerden 2003e, 644[VP]

Val Hall

Va.ri.ba′cu.lum. L. adj. *varus* bent, crooked; L. neut. n. *baculum* a small rod; N.L. neut. n. *Varibaculum* small bent rod.

Short, straight or curved diphtheroidal cells. Gram-stain-positive. Non-acid-fast. Non-spore-forming. Nonmotile. Facultatively anaerobic, may grow poorly in air and air plus 5% CO_2. Colonies are tiny, nondescript, and non-hemolytic. **Catalase-negative**. **End products of glucose metabolism are lactic and succinic acids with small amounts of acetic acid**. Acid is produced from glucose and some other sugars. **Hippurate is hydrolyzed**, but esculin, gelatin, and starch are not. Acetoin is not produced. Leucine arylamidase and α-glucosidase are weakly positive. Arginine dihydrolase, indole, pyrazinaminidase, and urease-negative. **Most isolates reduce nitrate to nitrite**. Major fatty acids are $C_{16:0}$, $C_{18:0}$, $C_{18:1}$ ω9*c*, and $C_{18:2}$ ω6,9*c*.

DNA G+C content (mol%): 51.7 (HPLC).

Type species: **Varibaculum cambriense** Hall, Collins, Lawson, Hutson, Falsen, Inganas and Duerden 2003e, 644[VP].

Further descriptive information

Phylogenetic analysis has demonstrated that the genus *Varibaculum* belongs to the high G+C Gram-stain-positive class *Actinobacteria* and is most closely related to, but clearly distinct from, the genera *Actinomyces*, *Actinobaculum*, *Arcanobacterium*, and *Mobiluncus*.

Cells are short, straight or curved Gram-stain-positive rods and form diphtheroid-like to almost completely ring-shaped arrangements. All forms may be seen in a single culture. Nonhemolytic, translucent white to gray, pinpoint, convex, entire edged, and glistening colonies are formed after anaerobic incubation for 48 h at 37°C on Fastidious Anaerobe Agar supplemented with 5% horse blood. Cultures grown in brain heart infusion broth incubated anaerobically at 37°C produce a granular sediment and an almost clear supernate. Optimal growth occurs under anaerobic conditions. Strains grow well or poorly in air plus 5% CO_2 and poorly or not at all in air. Good growth occurs on Fastidious Anaerobe Agar supplemented with 5% horse blood at neutral pH and at 35–37°C. Growth on other media and at other temperatures has not been examined.

Principal end products of glucose metabolism are lactic and succinic acids with small amounts of acetic acid. Acid is produced from D-glucose, D-ribose, and sucrose in conventional biochemical tests. Acid production from fructose, mannitol, and xylose is variable, but acid is not produced from amygdalin, L-arabinose, cellobiose, lactose, mannose, D-raffinose, salicin, or trehalose. Most strains reduce nitrate to nitrite; indole production is negative; neither lecithinase nor lipase are produced. Hippurate is hydrolyzed but not esculin, gelatin, or starch.

The almost complete 16S rRNA gene sequence of the type strain (CCUG 44998[T]) shares 99.1–100% similarity with several other *Varibaculum cambriense* strains and shows 10–12% divergence from *Actinomyces neuii* and *Mobiluncus* species, their nearest phylogenetic neighbors; other *Actinomyces* species and *Arcanobacterium* species are more distantly related. These relationships are supported by similar findings by Hoyles et al. (2004) and by whole-cell protein profiles obtained in SDS-PAGE analyses (Hall et al., 2003e).

Varibaculum cambriense is susceptible to benzylpenicillin, chloramphenicol, and imipenem and is resistant to metronidazole. Susceptibility to clindamycin, erythromycin, and tetracycline is variable. MICs demonstrate a bi-modal distribution as they are either sensitive or highly resistant. Clindamycin resistance is associated with erythromycin resistance.

Varibaculum cambriense has been isolated from various human soft-tissue infections in mixed cultures of anaerobic and aerobic bacteria. The roles of individual species in polymicrobial infections are difficult to ascertain and may involve complex interactions between component organisms, hence the pathogenicity of *Varibaculum cambriense* is not clear. In the United Kingdom and Scandinavia, this organism has been isolated from sebaceous cysts, pilonidal sinus, vagina, intrauterine contraceptive devices and from abscesses of the axilla, brain, breast, chest wall, ear, ischio-rectum, mastoid, mouth, and neck.

Isolation procedures

Varibaculum cambriense may be cultured on Fastidious Anaerobe Agar supplemented with 5–7% horse or sheep blood, and on Columbia Blood Agar or equivalent agars. For isolation from polymicrobial infections, culture on Actinomyces selective agar supplemented with metronidazole 10 mg/l and nalidixic acid 30 mg/l may be advantageous. Cultures should be incubated for a minimum of 48 h under anaerobic conditions at 35–37°C. Broth enrichment cultures are rarely useful due to overgrowth from other organisms.

Maintenance procedures

Viability has been maintained for >10 years in strains stored at –70°C in commercially available vials of beads or in brain heart infusion broth containing 10% glycerol. Reference strains held in culture collections are stored as lyophilized cultures.

Procedures for testing special characters

Commercially available identification systems. API Coryne, API Rapid 32A, API Rapid ID 32Strep, and API ZYM systems (BioMérieux, Marcy l'Étoile, France) may aid identification. However, *Varibaculum cambriense* is not listed in the manufacturer's databases hence results should be interpreted with reference to the findings of Hall et al. (2003e) or as listed below.

Amplified 16S rDNA restriction analysis (ARDRA). *Varibaculum cambriense* is reliably differentiated from other facultatively anaerobic non-sporeforming, Gram-stain-positive rods in ARDRA using universal 16S rDNA primers, namely AGAGTTTGATCCTGGCTCAG (pA) and AAGGAGGTGATCCAGCCGA (pH′) and endonucleases *Hae*III and *Hpa*II, as described by Hall et al. (1999).

Differentiation of the genus *Varibaculum* from other genera

Phylogenetically, *Varibaculum cambriense* is most closely related to *Mobiluncus* spp. and *Actinomyces neuii* and less closely to other *Actinomyces* spp., but it can be clearly differentiated from these

taxa by comparison of 16S rRNA gene sequences sharing only 91–92% similarity with its nearest relatives.

In phenotypic tests, *Varibaculum cambriense* is differentiated from *Mobiluncus* spp. by its lack of motility and in the API Rapid ID 32Strep system by its ability to hydrolyze hippurate (*Mobiluncus mulieris* is negative) and its negative reactions for α-galactosidase, β-galactosidase, and arginine dihydrolase, all of which are positive in *Mobiluncus curtisii*. An inability to produce catalase differentiates *Varibaculum* from *Actinomyces neuii* and other catalase-positive *Actinomyces* spp. and it is further distinguished from *Actinomyces neuii* by being negative for α-galactosidase, β-galactosidase, and pyrazinamidase. A combination of reactions in the API Rapid ID 32Strep system are useful to differentiate *Varibaculum cambriense* from catalase-negative, hippurate-hydrolyzing *Actinomyces* spp. isolated from human sources (see Table 19).

In ARDRA, as described above, *Varibaculum cambriense* isolates yielded one or other of the profiles designated 035/023 and 034/014 and were described as "unidentified actinomycete group 3" by Hall et al. (2001b). These profiles are distinct from those of *Actinomyces* spp., *Actinobaculum* spp., *Arcanobacterium* spp., *Mobiluncus* spp., *Gardnerella vaginalis*, and clinically relevant species of *Bifidobacterium*, *Lactobacillus*, and *Propionibacterium* (Hall et al., 2001a, 2001b).

TABLE 19. Differentiation of *Varibaculum cambriense* from catalase-negative, hippurate-hydrolyzing *Actinomyces* species isolated from human sources[a]

	V. cambriense	*A. funkei*	*A. hongkongensis*	*A. turicensis*
Acid from:[b]				
Lactose	–	+	–	–
Ribose	d	d	–	d
Sucrose	d	+	–	+
Trehalose	d	–	–	–
Production of:				
β-Galactosidase	d	d	–	–
Alkaline phosphatase	–	+	–	–
Alanine phenylalanine proline arylamidase	d	+	+	+
Nitrate reduction	+	d	–	–

[a]Symbols: +, >85% positive; d, different strains give different reactions (16–84% positive); –, 0–15% positive.

[b]Tests other than nitrate reduction were performed in the API Rapid ID 32Strep system.

Taxonomic comments

The genus *Varibaculum* was described by Hall et al. in 2003 to define a number of *Actinomyces*-like isolates from human clinical sources and it comprises a single taxon, originally defined as *Varibaculum cambriensis* (sic). The species epithet was corrected to *Varibaculum cambriense* upon its validation (*In* Validation of publication of new names and new combinations previously effectively published outside the IJSEM. List no. 91, 2003). *Varibaculum cambriense* remains the sole species. However, a small number of isolates have been found to be genotypically and phenotypically indistinguishable from *Varibaculum cambriense* except for their ability to rapidly hydrolyze urea. To date, these isolates have not been formally described as a distinct taxon.

List of species of the genus *Varibaculum*

1. **Varibaculum cambriense** Hall, Collins, Lawson, Hutson, Falsen, Inganas and Duerden 2003e, 644[VP]

cam.bri.en′se. N.L. neut. adj. *cambriense* pertaining to Cambria, the Latin name of Wales.

The characteristics are as described for the genus with the following additional information. With the API ZYM system, α-glucosidase and leucine arylamidase are positive; acid phosphatase, phosphoamidase, esterase C4, and ester lipase C8 are weakly positive or negative, and all other tests are negative. With the API Coryne system, acid is produced from D-glucose, maltose and sucrose; α-glucosidase is positive; acid production from D-ribose and D-xylose is variable; acid is not formed from glycogen, lactose, or mannitol. Alkaline phosphatase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, pyrolidonyl arylamidase, pyrazinamidase, and urease reactions are negative. With the API 32A system, proline arylamidase is positive; α-glucosidase and arginine-, phenylalanine-, leucine-, tyrosine-, and serine arylamidases are positive or weakly positive. β-galactosidase, nitrate reduction, and alanine-, glycine-, and histidine arylamidases are variable. Urease, arginine dihydrolase, α-galactosidase, β-6-phosphate-galactosidase, β-glucosidase, α-arabinosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, mannose, raffinose, indole, alkaline phosphatase, leucyl glycyl arylamidase, pyroglutamic acid arylamidase, glutamic acid decarboxylase, α-fucosidase, and glutamyl glutamic acid arylamidase are negative.

In a study of 23 clinical isolates, including the type strain, MICs were determined by the Etest. All isolates were susceptible to benzylpenicillin (range 0.032–1 mg/l), chloramphenicol (0.19–3), and imipenem (0.047–0.5). Eight isolates were susceptible to clindamycin, erythromycin, and tetracycline, eight were resistant to tetracycline but susceptible to clindamycin and erythromycin, four were resistant to clindamycin and erythromycin but susceptible to tetracycline. Three isolates, including the type strain, were resistant to clindamycin, erythromycin, and tetracycline. MICs (in mg/l) for the 23 isolates were: clindamycin MIC_{50} = 0.125, MIC_{90} = >256, range 0.016–>256; erythromycin MIC_{50} = 0.047, MIC_{90} = >256, range 0.016–>256; tetracycline MIC_{50} = 3.0, MIC_{90} = >256, range 0.5–>256.

DNA G+C content (mol%): 51.7 (HPLC).

Type strain: R12359, CCUG 44998, CIP 107344.

Sequence accession no. (16S rRNA gene): AJ428402, AJ491326.

Order II. **Actinopolysporales** ord. nov.

Michael Goodfellow and Martha E. Trujillo

Ac.ti′no.po.ly.spo.ra.les. N.L. fem. n. *Actinopolyspora* the type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Actinopolysporales* the *Actinopolyspora* order.

The order was formed by elevation of the suborder *Micromonosporineae* Zhi, Li and Stackebrandt 2009, 594[VP]. It contains the family *Actinopolysporaceae*. It is defined on the basis of its phylogeny in 16S rRNA gene trees and the **16S rRNA signature consisting of nucleotides at positions 127:234 (A–U), 242:284 (C–G), 657:749 (G–C), 672:734 (C–G), 828(A), 829:857 (G–C), 833–853 (U–G), 840:846 (C–G), 986:1219 (U–A), 1100 (U), 1183 (C), 1117:1183 (G–C) and 1309:1328 (G–U).**

Type genus: **Actinopolyspora** Gochnauer, Leppard, Komaratat, Kates, Novitsky and Kushner 1975, 1510[AL].

Family I. **Actinopolysporaceae** Zhi, Li and Stackebrandt 2009, 595[VP]

Michael Goodfellow and Martha E. Trujillo

Ac.ti′no.po.ly.spo.ra′ce.ae. N.L. fem. n. *Actinopolyspora* the type genus of the family; -*aceae*, ending to denote a family; N.L. fem. pl. n. *Actinopolysporaceae* the *Actinopolyspora* family.

The description is the same as for the genus *Actinopolyspora*. The 16S rRNA nucleotide signature is that of the order.

DNA G+C content (mol%): 64–68 (T_m, HPLC).

Type genus: **Actinopolyspora** Gochnauer, Leppard, Komaratat, Kates, Novitsky and Kushner 1975, 1510[AL].

Genus I. **Actinopolyspora** Gochnauer, Leppard, Komaratat, Kates, Novitsky and Kushner 1975, 1510[AL]

Martha E. Trujillo and Michael Goodfellow

Ac.ti.no.po.ly.spo′ra. Gr. n. *aktis* -*inos* ray; Gr. adj. *polus* many; Gr. fem. n. *spora* seed and in biology a spore; N.L. fem. n. *Actinopolyspora* the many-spored ray (fungus).

Aerobic, Gram-stain-positive, acid-fast, nonmotile actinomycetes that **form an extensively branched substrate mycelium about 1 μm in diameter**. Fragmentation of the substrate mycelium is occasionally observed near the colony center, but substrate hyphae are mostly non-fragmented. **Sporophores containing 10 or more smooth-walled coccobacillary and coccoid spores are produced basipetally on aerial hyphae.** Spores are not observed on the substrate mycelium. **Chemoorganotrophic and halophilic; 10–20% (w/v) NaCl is required for optimal growth. Temperature growth range is 30–50°C.** Whole-organism hydrolyzates contain *meso*-diaminopimelic acid (*meso*-A_2pm), arabinose, and galactose. Muramic acid moieties are *N*-acetylated. **Cells contain phosphatidylcholine as the diagnostic phospholipid and are rich in branched-chain fatty acids, notably $C_{17:0}$ anteiso and $C_{15:0}$ iso, but lack mycolic acids. The predominant menaquinones are MK-9(H_4) and MK-9(H_6).**

DNA G+C content (mol%): 64–68 (HPLC, T_m).

Type species: **Actinopolyspora halophila** Gochnauer, Leppard, Komaratat, Kates, Novitsky and Kushner 1975, 1510[AL].

Further descriptive information

Phylogeny. The genus *Actinopolyspora* currently contains three species with validly published names: *Actinopolyspora halophila*, *Actinopolyspora iraqiensis*, and *Actinopolyspora mortivallis*. The three species are moderately related based on 16S rRNA gene sequence analysis (Figure 59). *Actinopolyspora halophila* and *Actinopolyspora mortivallis*, the most closely related species, share a sequence similarity of 96.7%. *Actinopolyspora iraqiensis* shares 16S rRNA gene sequence similarities of 89.3% and 89.7% with *Actinopolyspora halophila* and *Actinopolyspora mortivallis*, respectively. It shows a much closer phylogenetic relationship with *Saccharomonospora halophila* and *Saccharomonospora paurometabolica* (98.9–99.0%) and probably belongs to this genus. *Actinopolyspora halophila* and *Actinopolyspora mortivallis* share a DNA–DNA relatedness value of 34% (Yoshida et al., 1991). A thermophilic species, "*Actinopolyspora thermovinacea*" was described by Lu and Yan (1983), but the name has not been validly published.

Cell morphology. Strains currently classified in the genus *Actinopolyspora* produce well developed, irregularly branched,

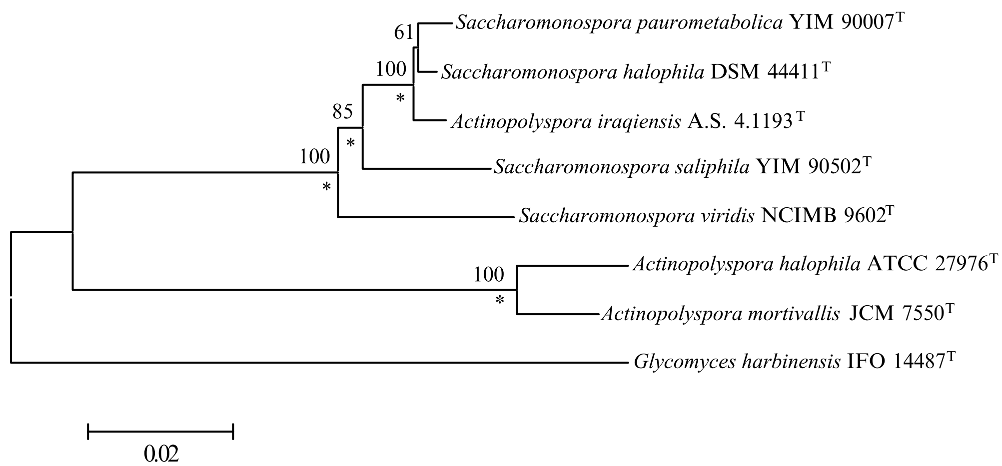

FIGURE 59. Neighbor-joining tree based on almost complete 16S rRNA gene sequences showing relationships between *Actinopolyspora* species and related taxa. Asterisks indicate branches of the tree that were also recovered using the maximum-parsimony tree-making algorithm. Numbers at the nodes indicate the levels of bootstrap support based on a neighbor-joining analysis of 1000 resampled datasets. *Glycomyces harbinensis* IFO 14487[T] was used as the outgroup. Bar = 2 substitutions per 100 nucleotides.

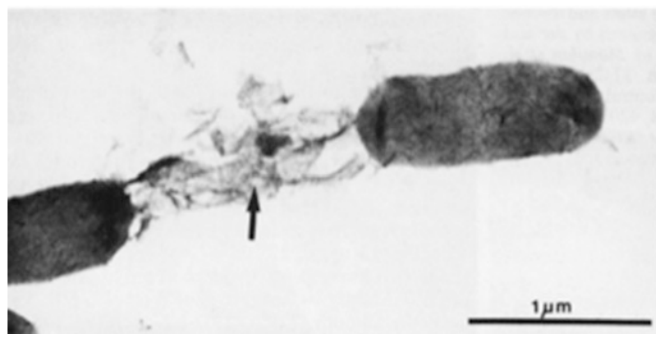

FIGURE 62. Negatively stained aerial hypha of *Actinopolyspora halophila* ATCC 27976ᵀ with sheath, partially detached (arrow). TEM. (Reproduced with permission from Kothe et al., 1989. Syst. Appl. Microbiol. *12*: 61–69.)

substrate hyphae (0.4–1.0 μm in diameter) which rarely fragment, although *Actinopolyspora halophila* may show fragmentation near the centers of colonies. Spores are produced on aerial hyphae, but have not been observed on the substrate mycelium. Sporophores containing 20 or more smooth-walled coccobacillary and coccoid spores (0.7–1 × 1–2 μm) are produced basipetally on aerial hyphae in *Actinopolyspora halophila*. Straight to flexuous chains of 10 or more spores are formed by *Actinopolyspora mortivallis*; the spores are oval to cylindrical (0.5–0.7 × 0.8–1.3 μm) and have smooth surfaces. *Actinopolyspora iraqiensis* forms short chains of spores (1–15) that are spherical (1 μm in diameter) and have smooth surfaces.

Fine structure. The fine structure of *Actinopolyspora halophila* has been examined using transmission and scanning electron microscopy (Gochnauer et al., 1975; Kothe et al., 1989). The mycelium at the air-surface interface consists of long cylindrical filaments that are about 1 μm in diameter and which terminate in rounded tips (Figure 60); branching occurs at either acute or right angles to the main filament. Not all branches have the same diameter as the main filament; irregular branching patterns include some opposite branching. Filaments frequently have several bands or pronounced curvatures, and some are helical. Cross walls have not been detected in vegetative filaments. Ropelike aggregates of vegetative filaments are frequently formed on agar media containing 10% (w/v) NaCl (Figure 61), but rarely on media containing 30% (w/v) NaCl.

Aerial hyphae are enclosed by an outer sheath (Figure 62) which corresponds to the sheath of *Streptomyces* (Williams et al., 1972). Long chains of smooth spores are formed on the aerial mycelium (Figure 63). Small cells may be observed between mature spores in ultrathin sections (Figure 64 and Figure 65). Some (possibly immature) sporophores are branched. Spores vary in size and shape within a single sporophore. They may be spherical to short rods with rounded ends. The spore morphology of cultures grown on agar media containing 12.5 or 15.0% (w/v) NaCl is similar to that of strains grown in the presence of 20% (w/v) NaCl. Spores are not formed on media containing 25% (w/v) NaCl, but are produced, albeit infrequently, on media containing 10% (w/v) NaCl.

Colony morphology. Actinopolysporae grow well on a variety of culture media. *Actinopolyspora halophila* forms wrinkled colonies covered with white aerial hyphae and a buff colored substrate mycelium on the complex medium of Sehgal and Gibbons (1960) supplemented with 15% (w/v) NaCl. The color of the substrate mycelium is influenced by the salt concentration and becomes darker with reduced salt; at a concentration of 10% (w/v) salt, the substrate mycelium is black (Gochnauer et al., 1975). A diffusible brown pigment is formed on low salt medium. *Actinopolyspora iraqiensis* forms small, thin, elevated to convex colonies (2–4 mm in diameter) that are covered by white aerial hyphae when grown on agar media containing 10–15 (w/v) salt; the substrate mycelium is yellowish to brownish (Ruan et al., 1994). *Actinopolyspora mortivallis* forms yellowish white colonies and a pale diffusible pigment on oatmeal agar (Yoshida et al., 1991).

Actinopolysporae grow best under aerobic conditions. If stab-inoculated into soft agar media, *Actinopolyspora halophila* grows

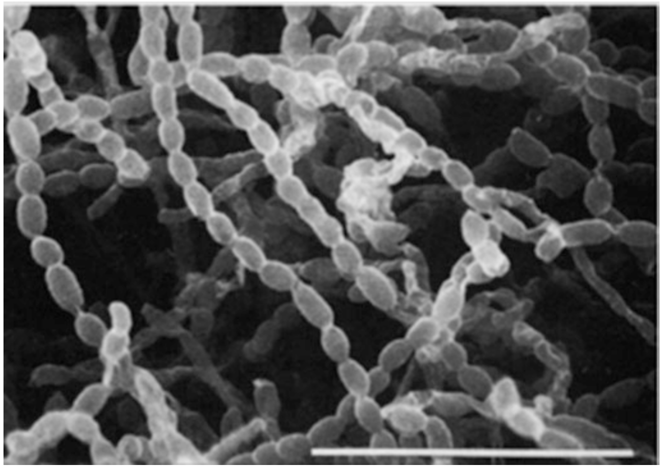

FIGURE 63. Aerial hyphae of *Actinopolyspora halophila* ATCC 27976[T] with chains of smooth spores. SEM. (Reproduced with permission from Kothe et al., 1989. Syst. Appl. Microbiol. *12*: 61–69.)

only at the surface. Growth of the organism in liquid media is proportional to the degree of aeration; in stationary cultures, growth occurs on the surface as a wrinkled hydrophobic pellicle.

Chemotaxonomy. *Actinopolyspora* strains have cell walls that contain *meso*-A_2pm, arabinose, and galactose, i.e., they have a wall chemotype IV *sensu* Lechevalier and Lechevalier (1970). In addition, *Actinopolyspora iraqiensis* contains traces of LL-A_2pm and ribose (Ruan et al., 1994). Almost all the available glycan disaccharide units are peptide substituted in the walls of *Actinopolyspora halophila* strains; peptide cross-linkage is facilitated by direct peptide linkage between N^E-A_2pm and COOH-terminal alanine. The peptidoglycans of *Actinopolyspora halophila* WT (wild-type) and ER (mutant) strains are 50 and 67% peptide cross-linked, respectively. The WT strain contains 15.7% non-*N*-substituted muramic acid and 35% non-*N*-substituted glucosamine; corresponding figures for the ER strain are 11 and 48.8%, respectively (Johnson et al., 1986b). In addition, the walls of both the wild-type and the mutant strains contain glutamic acid, alanine, and A_2pm in the molar ration 1:2:1. There is also evidence of a direct cross-linkage between A_2pm and the terminal D-alanine in the intact peptidoglycan (type A1γ; Schleifer and Kandler, 1972) and for a wall-associated arabino-galactan polymer. The type strain of *Actinopolyspora halophila* contains a number of ester-linked phospholipids, as well as glycolipids and neutral lipids, but lacks ether-linked phospholipids (Ross et al., 1981).

Actinopolysporae contain major amounts of phosphatidylcholine (taxonomically significant polar lipid), diphosphatidylglycerol, phosphatidylglycerol, and *lyso*-phosphatidylglycerol (Embley et al., 1988b; Gochnauer et al., 1975; Kothe et al., 1989; Ruan et al., 1994) and, hence, they have a phospholipid type III *sensu* Lechevalier et al. (1981, 1977). They are rich in branched-chain fatty acids (Gochnauer et al., 1975; Kothe et al., 1989; Yoshida et al., 1991), but lack mycolic acids (Kates et al., 1987; Minnikin and Goodfellow, 1980; Ruan et al., 1994; Yoshida et al., 1991). The predominant menaquinone is MK-9(H_4), although *Actinopolyspora halophila* and *Actinopolyspora mortivallis* also contain MK-10(H_4) (Embley et al., 1988b; Yoshida et al., 1991), and *Actinopolyspora iraqiensis* also contains MK-9(H_6) (Ruan et al., 1994). The electrophoretic mobilities of ribosomal AT-L30 proteins of the type strains of *Actinopolyspora halophila* and *Actinopolyspora mortivallis*, determined by two dimensional PAGE, have been shown to be similar (Ochi and Yoshida, 1991).

Nutrition and growth conditions. *Actinopolyspora* strains require salt for growth. On solid media, growth occurs in the presence of 5–30% (w/v) NaCl, with optimal growth in media containing 10 and 20% (w/v) NaCl. Growth does not occur in media containing 5% (w/v) NaCl. *Actinopolyspora halophila* strain WT (wild-type) is extremely halophilic: it needs at least 12% (w/v) NaCl to grow in liquid medium and 10% (w/v) NaCl to grow on agar medium. It grows well in the presence of 15–20% (w/v) NaCl and can be cultivated in media containing 30% (w/v) NaCl. In contrast, mutant *Actinopolyspora halophila*

strain ER can grow in 6% (w/v) complex medium (CM*) broth (Gochnauer and Kushner, 1969; Sehgal and Gibbons, 1960). These strains can be washed in distilled water without loss of viability. Salt cannot be effectively replaced by KCl. On CM agar, the WT strain grows and sporulates at pH 6.0–8.6. Strain ER grows from pH 5.0 to 8.6 (poorly at higher pH) though sporulation is slow and occurs only from pH 6.0 to 7.0.

Optimal growth of the type and mutant strains of *Actinopolyspora halophila* occurs at 37°C in shake flasks containing CM broth (Sehgal and Gibbons, 1960) supplemented with 20% (w/v) NaCl (Johnson et al., 1986a). Good growth is usually achieved within 14 d, but there may be a long lag phase followed by rapid growth. Lysis may occur in stationary phase cultures. *Actinopolyspora mortivallis* shows abundant growth on nutrient, oatmeal, potato-glucose, sucrose-nitrate, and yeast extract-malt extract agars, and moderate growth on peptone-yeast extract-iron agar, but grows poorly on glucose-asparagine agar (Yoshida et al., 1991). *Actinopolyspora iraqiensis* grows well on modified complex medium (SGA†). Actinopolysporae grow between 30 and 50°C (Ruan et al., 1994).

Metabolism and genetics. Actinopolysporae have a chemoorganotrophic metabolism and are able to use diverse carbon sources, including fructose, galactose, glucose, glycerol, maltose, mannitol, raffinose, rhamnose, sucrose, xylose, isopropyl alcohol, sodium citrate, and sodium succinate. *Actinopolyspora mortivallis*, unlike *Actinopolyspora halophila*, degrades xylan and peptonizes milk, but is unable to reduce nitrate, it also has a distinctive temperature range and carbon utilization profile (Yoshida et al., 1991). An *Actinopolyspora* strain isolated from a salt marsh off the southeast coast of India was found to be resistant to mercury (Senthilkumar et al., 2005).

Actinopolyspora halophila synthesizes a range of extracellular enzymes when grown in CM broth containing 15% (w/v) NaCl; these include α-amylase, carboxymethylcellulase, proteases, and a xylanase (Johnson and Lanthier, 1986; Johnson et al., 1986a). The production of the carboxymethylcellulase and xylanase is enhanced by the presence of xylan. Cells grown in CM supplemented with lactose synthesize calcium-dependent (0.1 mM) cellular and extracellular β-galactosidase and 6-phospho-β-galactosidase. Both of these enzymes and a cellular glutamate dehydrogenase are NADP-dependent; it has also been shown that succinate dehydrogenase uses either NAD or NADP. *Actinopolyspora halophila* also produces a cellular and an active exocellular β-lactamase (Johnson and Lanthier, 1986). These enzymes degrade compounds containing 6-aminopenicillanic acid (including methicillin) and 6-aminocephalosporanic acid. It has also been shown that these enzymes are stimulated in their activities and protected from thermal denaturation by NaCl. "*Actinopolyspora thermovinacea*" is thermophilic (Lu and Yan, 1983).

Halophilic bacteria living in high salt concentrations accumulate small organic compounds in order to balance the osmotic pressure. These molecules have been named compatible solutes because of their compatibility with cellular metabolism at high concentrations (Brown, 1976). Glycine betaine (betaine), the best-known compatible solute, is synthesized from simple carbon sources by halophilic and halotolerant phototrophic bacteria and by extremely halophilic methanogenic archaea, an ability that is rare among heterotrophic bacteria. In an extensive study using ^{13}C-NMR, Severin et al. (1992) found that *Actinopolyspora halophila* and a related isolate were the only heterotrophic strains in which *de novo* synthesis of betaine could be detected. They also found that trehalose, like betaine, was present in the compatibility solute pool of *Actinopolyspora halophila*. It was subsequently shown that *Actinopolyspora halophila* synthesized betaine by threefold methylation of glycine with *S*-adenosylmethionine acting as the methyl group donor (Nyyssölä et al., 2000). *Actinopolyspora halophila* oxidizes choline to betaine and appears to be the only bacterium that is able to do this and use the glycine methylation pathway for *de novo* synthesis of betaine (Nyyssola and Leisola, 2001). These workers also found that trehalose was synthesized as a compatible solute and accounted for up to 9.7% of the cellular dry weight. The betaine concentration was shown to rise with increasing NaCl concentration, whereas that of trehalose was highest at the lowest concentration (15%, w/v).

Actinopolyspora strain YIM 90600, a putatively novel member of the genus *Actinopolyspora*, was isolated from a dried salt lake in Xinjiang Province, northwest China, and shown to produce erythronolides H and I, new erythromycin congeners (Huang et al., 2009). The authors noted that the presence of the C-14 hydroxyl moieties and the C-6/C-18-epoxide in erythronolide H and the spiroketal moiety of erythronolide I shed new insights into the structural diversity of erythromycin analog libraries that might be accessible by combinatorial biosynthesis. The organism was also shown to produce a high titer of erythromycin C.

The genetics of *Actinopolyspora* have received little attention. Erythromycin resistance in *Actinopolyspora halophila* strain ER is genetically stable, but neither this strain nor the wild-type strain was found to contain plasmids (Johnson et al., 1986a). Holes which resemble viral plaques appear most frequently in colonies grown at lower NaCl concentrations suggesting the presence of bacteriophages, but no phage has been isolated (Gochnauer et al., 1975).

Antibiotic sensitivity. *Actinopolyspora halophila* is highly resistant to β-lactam antibiotics, but is sensitive to amoxycillin. The antibiotic sensitivity profiles of individual *Actinopolyspora* species are given in the species descriptions.

Ecology. *Actinopolyspora* strains have been isolated from hypersaline environments, including salt marsh soil and marine sediments (Kokare et al., 2004; Senthilkumar et al., 2005; Vijayakumar et al., 2007). *Actinopolyspora halophila* was recovered as a contaminant in a culture medium containing 25% NaCl (Gochnauer et al., 1975), *Actinopolyspora mortivallis* was from a salty soil sample collected in Death Valley, California (Yoshida et al., 1991), and *Actinopolyspora iraqiensis* was from an extremely saline soil sample in Iraq (Al-Tai and Ruan, 1994; Ruan et al., 1994). *Actinopolyspora* strains identified by 16S rRNA gene sequencing have been isolated from salt-lakes in China (Huang et al., 2009; Zhi et al., 2007). "*Actinopolyspora thermovinacea*" was isolated from soil samples (Lu and Yan, 1983).

*Complex medium (all ingredients except Fe^{2+} given in g/l): Difco Casamino acids (vitamin free), 7.5; Difco yeast extract, 10.0; $MgSO_4 \cdot 7H_2O$, 10.0; sodium citrate, 3.0; KCl, 1.0; NaCl, 200; Fe^{2+}, prepare 4.98% $FeSO_4 \cdot 7H_2O$ (10,000 ppm Fe^{2+}; 0.001 M in HCl; add 1 ml/l medium). Adjust to pH 6.8 and sterilize at 15 lbs pressure for 10 min. For tryptone medium, substitute 1.5 g Difco tryptone for Casamino acids-yeast extract. Also, 27.5 g Difco trypticase-soy broth can be substituted for casamino acids and yeast extract. All support good growth.

†Modified complex medium (per liter): Difco Casamino acids, 7.5 g; Difco yeast extract, 10.0 g; $MgSO_4 \cdot 7H_2O$, 20 g; sodium citrate, 3.0 g; KCl, 2.0 g; NaCl, 200 g; plus 1 ml of a trace salts solution (0.1 g $FeSO_4 \cdot 7H_2O$, $MnCl_2 \cdot 4H_2O$, and $ZnSO_4 \cdot 4H_2O$ in 1 liter distilled water).

Isolation procedures

Actinopolyspora halophila was initially recognized as a contaminant in a flask of nonsterile CM broth containing 25% (w/v) solar salt. The broth was left to stand at room temperature for 50 d when *Actinopolyspora halophila* was observed as a surface mycelial mat (Gochnauer et al., 1975). The organism may well have been a contaminant of the solar salt which suggests that it might occur in salt ponds (salterns) where sea salt is harvested. It may also occur in muds and soils adjacent to salterns and salt lakes. The procedures used to isolate *Actinopolyspora iraqiensis* and *Actinopolyspora mortivallis* were not given in the original publications (Ruan et al., 1994; Yoshida et al., 1991). "*Actinopolyspora thermovinacea*" was isolated from soil samples (Lu and Yan, 1983).

The following procedure was suggested by Gochnauer et al. (1989) for the selective isolation of actinopolysporae from saline habitats. Cells are washed thoroughly with distilled water to eliminate osmotically sensitive halobacteria and other microorganisms, collected on membrane filters and incubated on an agar medium containing 20% (w/v) NaCl and the basic minerals in CM medium plus low concentrations of yeast extract (1–2%, w/v) and Casamino acids (0.1%, w/v); cycloheximide is added to inhibit the growth of salt-tolerant and halophilic eukaryotic cells. The medium is adjusted to pH 6.5–7.0 and the inoculated plates are incubated at 35–40°C in plastic bags to provide a humid atmosphere. For enrichment, stationary liquid cultures in the same medium should be incubated for up to 6 weeks. Typical white mycelial growth on the surface and on the walls at the air-liquid interface should be examined, diluted, and plated on solid medium of the same formulation (2% agar) until pure cultures are obtained.

Maintenance procedures

Well grown cultures may be stored for up to a year in screw-capped tubes at 4°C in CM agar containing 15–20% (w/v) NaCl. Such cultures can also be maintained at −70°C and, on thawing, should be grown on fresh CM agar for three successive 72–96 h periods prior to use. For longer term preservation, cultures may be lyophilized. Cells are grown to the beginning of the stationary phase, centrifuged, and suspended in the following medium: Dextran T-500 (Pharmacia), 5 g; sucrose, 9.5 g; monosodium glutamate, 1.0 g; NaCl, 20 g; and distilled water to a final volume of 100 ml. After the ingredients are dissolved, the medium is dispensed into tubes and sterilized at 121°C for 15 min. Cells are then resuspended in the same medium, and 1–2 ml suspension per ampoule is frozen in acetone-dry ice. Because of the high NaCl concentration, it is especially important to coat the inside of ampoules with a very thin layer of frozen material before applying a vacuum in order to ensure complete lyophilization.

Differentiation of the genus *Actinopolyspora* from other genera

The genus *Actinopolyspora* is phylogenetically different from other genera with a type IV cell wall containing *meso*-A_2pm, arabinose, and galactose. It can be differentiated as it forms a deep branch in the 16S rRNA gene tree and hence can be readily distinguished from other genera classified in the order *Actinomycetales* (Zhi et al., 2009), including those which encompass strains with a wall chemotype IV. Zhi and his colleagues also noted that members of the genus shared unique 16S rRNA gene signatures. In addition, *Actinopolyspora*-specific oligonucleotide primers are available for the identification of members of the genus (Zhi et al., 2007). Actinopolysporae can also be distinguished from other actinomycetes which produce long chains of spores on the aerial mycelium by using chemical markers (Embley et al., 1988b; Yoshida et al., 1991), on the basis of the electrophoretic mobilities of their ribosomal AT-L30 proteins (Ochi, 1995b) and by partial amino acid sequencing of the AT-L30 protein (Ochi, 1995a). The genus has traditionally been separated from other sporoactinomycetes by its requirement for high salt concentrations for growth (Gochnauer et al., 1975; Yoshida et al., 1991), although the reliability of this feature can be questioned as a mutant of the type strain of *Actinopolyspora halophila* only requires 6% (w/v) NaCl for growth (Johnson et al., 1986a).

Taxonomic comments

The genus *Actinopolyspora* was proposed by Gochnauer et al. (1975) to accommodate an extremely halophilic strain that had been isolated as a contaminant from CM broth containing 25% (w/v) NaCl. The chemotaxonomic and morphological properties of the organism led to its assignment to the family *Nocardiaceae* which, at the time, contained an assortment of actinomycetes that included the genera *Micropolyspora*, *Mycobacterium*, *Nocardia*, *Pseudonocardia*, *Saccharopolyspora*, and *Thermomonospora* (Lacey and Goodfellow, 1975; Lechevalier et al., 1971, 1973). The genus was classified with the "nocardioform actinomycetes" in the last edition of *Bergey's Manual of Systematic Bacteriology* (Lechevalier, 1989). It subsequently became a founder member of the family *Pseudonocardiaceae* Embley et al. (1988a), together with the genera *Amycolatopsis*, *Faenia*, *Pseudonocardia*, *Saccharomonospora*, and *Saccharopolyspora*. These taxa, which have wall chemotype IV and contain MK-9(H_4) as the predominant isoprenolog, were considered to form a coherent phylogenetic group based on reverse transcriptase sequencing of 16S rRNA. The genus *Kibdelosporangium* was later added to the family (Bowen et al., 1989).

Stackebrandt et al. (1997) retained *Actinopolyspora* in the family *Pseudonocardiaceae* in their proposal for a new hierarchic classification of actinobacteria based on 16S rRNA gene sequences even though the genus had been separated from other wall chemotype IV actinomycetes that lacked mycolic acids by PAGE of ribosomal AT-L30 preparations and partial amino acid sequencing of ribosomal protein AT-L30 (Ochi, 1995b; Ochi and Yoshida, 1991). In addition to the genus *Actinopolyspora*, the revised family *Pseudonocardiaceae* (Warwick et al., 1994) emend. Stackebrandt et al. (1997) included the genera *Actinosynnema*, *Amycolatopsis*, *Kibdelosporangium*, *Kutzneria*, *Saccharomonospora*, *Saccharopolyspora*, *Saccharothrix*, *Streptoalloteichus*, and *Thermocrispum*. The introduction of the family *Actinosynnemataceae* by Labeda and Kroppenstedt (2000) to encompass the genera *Actinosynnema*, *Lenztia*, and *Saccharothrix* left the family *Pseudonocardiaceae* as a more homogeneous taxon. However, it is now apparent from 16S rRNA gene sequence studies that the genus *Actinopolyspora* is not related to members of the family *Pseudonocardiaceae* and merits recognition as the sole member of the family *Actinopolysporaceae* in the order *Actinopolysporales*, formerly suborder *Actinopolysporineae* (Zhi et al., 2009).

The genus *Actinopolyspora* currently contains three species with validly published names, i.e., *Actinopolyspora halophila* (Gochnauer et al., 1975), the type species, *Actinopolyspora iraqiensis* (Ruan et al., 1994), and *Actinopolyspora mortivallis* (Yoshida et al., 1991). However, it seems likely that *Actinopolyspora iraqiensis* is misclassified as it falls into the *Saccharomonospora* 16S rRNA gene clade (Figure 59).

TABLE 20. Differential characteristics of the type strains of *Actinopolyspora* species[a]

Characteristic	*Actinopolyspora halophila*	*Actinopolyspora mortivallis*	"*Actinopolyspora iraqiensis*"
Spore-chain morphology	Long (around 20), elongated	Short (≤10), oval to cylindrical	Short (≤15), spherical
Color of colony in 10% (w/v) NaCl	Black	Yellowish white	Pale brown
Soluble pigments (in 10% NaCl)	Black	Pale brown	None
Growth in (w/v) NaCl:			
5%	–	+	+
25%	+	+	–
NaCl concentration for optimum growth (%, w/v)	15–20	10–15	10–15
Sensitivity to[b]*:*			
Amoxycillin	S	R	S
Clindamycin	S	S	R
Vancomycin	S	S	R
Hydrolysis of carboxymethylcellulose	+	nd	–
Acid production from:			
L-Arabinose	–	–	–
Fructose	–	nd	–
Inositol	–	–	–
Mannitol	–	–	+
Rhamnose	–	–	–
Xylose	–	–	–
Growth at 42°C	+	+	–

[a] Modified from Ruan et al. (1994). +, Positive; –, negative; nd, not determined.

[b] S, Sensitive; R, resistant.

Differentiation of the species of the genus *Actinopolyspora*

Actinopolyspora species can be distinguished from one another by using a combination of morphological, nutritional, and physiological characteristics (Table 20). The type strains are also readily distinguished by 16S rRNA gene sequencing.

List of species of the genus *Actinopolyspora*

1. **Actinopolyspora halophila** Gochnauer, Leppard, Komaratat, Kates, Novitsky and Kushner 1975, 1510[AL]

ha.lo′phi.la. Gr. n. *hals halos* salt; Gr. adj. *philos* loving; N.L. fem. adj. *halophila* salt-loving.

An extensively branched substrate mycelium is formed (1 µm in diameter) which does not penetrate agar surfaces. Fragmentation is observed occasionally in the center of colonies. Straight sporophores composed of 20 or more smooth-walled spores are produced basipetally on aerial hyphae. Spores vary in size and shape within a single sporophore, but are not formed on the substrate mycelium. Colonies have a wrinkled appearance and produce white aerial mycelium in CM medium; the substrate mycelium is buff at high salt concentrations, darker at lower concentrations, and black in the presence of 10% (w/v) NaCl. Growth does not occur on solid or in liquid CM medium when NaCl is replaced with 30% (w/v) KCl. The temperature growth range is 10–43°C and the optimal growth temperature is 37°C.

The most distinctive characteristic of the organism is its absolute requirement for at least 10–12% (w/v) NaCl for growth; optimal growth occurs with 20% (w/v) NaCl. When grown in liquid shake culture in CM supplemented with 1% (w/v) starch and 20% (w/v) NaCl, a pineapple-like odor is produced; the odor is musty when the organism is grown in the presence of nutrients such as casein and yeast extract, 1% (w/v) tryptone, or 1% (w/v) trypticase soy.

Does not hydrolyze urea. Degrades casein, gelatin, and Tweens 20, 40, 60 and 80, but not starch or xanthine. Arabinose, fructose, inositol, mannitol, rhamnose, and xylose are used as sole carbon sources.

The organism is sensitive to lysozyme and to (IU) amikacin (30), amoxycillin (30), bacitracin (10), cefamandole (30), cefoxitin (30), chloramphenicol (30), clindamycin (2), erythromycin (15), gentamicin (10), kanamycin (30), naladixic acid (30), novobiocin (30), and vancomycin (30).

Additional phenotypic properties are cited in Table 20.

Whole-organism hydrolyzates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{15:0}$ iso (20%), $C_{16:0}$ iso (14%), $C_{17:0}$ iso (11%), and $C_{17:0}$ anteiso (32%), and smaller proportions (<10%) of $C_{16:0}$ (2%), $C_{16:1}$ (2%), $C_{17:0}$ (2%), $C_{18:0}$ iso (3%), and $C_{15:0}$ anteiso (8%). Does not contain mycolic acids. The polar lipid pattern contains phosphatidylcholine, phosphatidylglycerol, *lyso*-phosphatidylglycerol, and two glycolipids. The predominant menaquinones are MK-9(H_4) (65%) and MK-10(H_4) (22%); also contains minor proportions of MK-8(H_4), MK-9(H_2), and MK-9(H_6).

Source: isolated from contaminated CM medium supplemented with 25% (w/v) NaCl.

DNA G+C content (mol%): 64–68 (HPLC, T_m).

Type strain: ATCC 27976, DSM 43834, IFO (now NBRC) 14106, JCM 3278, VKM Ac-871.

Sequence accession no. (16S rRNA gene): X54287.

Additional comments: Actinopolyspora halophila strain ER was detected when the type strain was screened against 15 µg/ml erythromycin (Johnson et al., 1986a). The colonial and cell morphology of mutant strain ER was indistinguishable from

that of the parent strain, it had the same optimal growth temperature and grew over the same range of NaCl concentrations though its minimal NaCl concentration for growth is 6% (w/v) whereas that for the type strain is 12% (w/v). *Actinopolyspora halophila* ER is resistant to (IU) cefamandole (30), clindamycin (2), and erythromycin (15). Optimal growth is at pH 6.0–7.0, but unlike strain WT it grows at pH 5.0.

2. **Actinopolyspora mortivallis** Yoshida, Matsubara, Kudo and Horikoshi 1991, 19[VP]

mor.ti.val′lis. L. gen. n. *mortis* of death; L. gen. n. *vallis* of the valley; N.L. gen. n. *mortivallis* of Death Valley, the source of the soil sample from which the type strain was isolated.

A well developed, nonfragmenting, irregularly branched mycelium (0.4–0.6 µm in diameter) is formed. The aerial mycelium is branched monopodially and forms spore chains with more than 10 spores per chain. The spores are oval to cylindrical (0.5–0.7 × 0.8–1.3 µm) with smooth surfaces. Colonies on oatmeal (ISP medium 3) and potato-glucose agars are yellowish white, but are pinkish white on yeast extract-malt extract agar (ISP medium 2). A diffusible pale brown pigment is produced on oatmeal, nutrient, and peptone-yeast extract-iron agars.

The NaCl tolerance range is 5–30% (w/v), with optimal growth occurring in the presence of 10–15% (w/v) NaCl. The growth temperature range is 10–50°C, with optimal growth occurring at 45°C.

Milk is peptonized. Does not hydrolyze urea or reduce nitrate. Degrades casein, gelatin, Tweens 20, 40, 60 and 80, and xanthine. Fructose, glucose, raffinose, sucrose, and xylose are used as sole carbon sources, but not arabinose, inositol, mannitol, or rhamnose.

Susceptible to (µg/ml) ampicillin (10), carbenicillin (100), cephalothin (10), chloramphenicol (100), erythromycin (<10), methicillin (100), novobiocin (100), penicillin G (10), and vancomycin (100).

Additional phenotypic properties are cited in Table 20.

Whole-organism hydrolyzates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{15:0}$ iso (16%), $C_{16:0}$ iso (18%), $C_{17:0}$ iso (28%), and $C_{17:0}$ anteiso (29%), and minor proportions of $C_{17:0}$ (2%) and $C_{15:0}$ anteiso (3%). Does not contain mycolic acids. The polar lipid pattern includes phosphatidylcholine. The predominant menaquinones are MK-9(H_4) (32%) and MK-10(H_4) (47%); minor amounts of MK-8(H_4), MK-9(H_2), and MK-10(H_2) are also present.

Source: the type strain was isolated from a soil sample collected in Death Valley, California.

DNA G+C content (mol%): 68.0 (HPLC).

Type strain: HS-1, ATCC 49777, DSM 44261, IFO (now NBRC) 15162, JCM 7550, VKM Ac-1974.

Sequence accession no. (16S rRNA gene): DQ883812.

Species *incertae sedis*

1. **Actinopolyspora iraqiensis** Ruan, Al-Tai, Zhou and Qu 1994, 760[VP]

ira.qi.en′sis. N.L. fem. adj. *iraqiensis* of or belonging to Iraq, the source of the soil sample from which the organism was isolated.

Well developed/branched substrate mycelium (0.5–0.7 µm in diameter) which rarely fragments in either solid or liquid media. Aerial hyphae differentiate into short chains of 1–15 spherical spores (1 µm in diameter) with smooth surfaces.

Colonies are small (2–4 mm in diameter), thin, elevated, or convex. The aerial spore mass is white and appears abundant on modified complex solid medium containing 10–15% (w/v) NaCl. The reverse side of colonies is yellow to brownish; diffusible pigments are not formed. Optimal growth occurs when culture media are supplemented with 10–15% (w/v) NaCl. Does not grow in the presence of 25% (w/v) salt or in the absence of salt. The optimal growth temperature is between 30 and 35°C; grows poorly at 16 and 40°C, does not grow at 42°C.

Neither esculin nor urea are hydrolyzed. Degrades starch, tyrosine, Tween 80, and xanthine, but not cellulose. L-Arabinose, fructose, galactose, glucose, inositol, maltose, mannitol, raffinose, and sucrose are used as sole carbon sources, but not mannose, L-rhamnose, or xylose.

Sensitive to lysozyme and to amoxycillin, bacitracin, carbenicillin, cephalexin, chloramphenicol, erythromycin, and novobiocin, but resistant to clindamycin, oxacillin, and vancomycin. Shows antimicrobial activity against *Saccharomyces pombe*.

Additional phenotypic properties are cited in Table 20.

The cell wall contains *meso*-A_2pm and trace amounts of L-A_2pm. Whole-organism hydrolyzates contain arabinose, galactose, and ribose. Does not contain mycolic acids. The polar lipid pattern includes diphosphatidylglycerol, *lyso*-diphosphatidylglycerol, phosphatidylcholine, and phosphatidylglycerol. The predominant menaquinone is MK-9(H_4).

Source: isolated from saline soil collected in Iraq.

DNA G+C content (mol%): not determined.

Type strain: IQ-H1, CCIM A.S. 4.1193, DSM 44640, JCM 9891, NBRC 103187.

Sequence accession no. (16S rRNA gene): EF372523.

Stackebrandt, E., F.A. Rainey and N.L. Ward-Rainey. 1997. Proposal for a new hierarchic classification system, *Actinobacteria* classis nov. Int. J. Syst. Bacteriol. *47*: 479–491.

Family I. **Bifidobacteriaceae** Stackebrandt, Rainey and Ward-Rainey 1997, 487[VP]

Bruno Biavati

Bi.fi.do.bac.te.ri.a.ce′a.e. N.L. neut. n. *Bifidobacterium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Bifidobacteriaceae* the *Bifidobacterium* family.

The pattern of 16S rRNA gene signatures consists of nucleotides at positions 122:239 (G–U), 128:233 (C–G), 450:483 (C–G), 602:636 (G–C), 681:709 (C–G), 688:699 (A–U), 823:877 (A–U), 1118:1155 (C–G), and 1311:1326 (A–U).

The delineation of this bacterial family is based on phylogenetic criteria supported by biochemical characteristics such as phosphoketolase activity. The family contains the genera *Bifidobacterium* (32 species), *Alloscardovia* (one species), *Aeriscardovia* (one species), *Metascardovia* (one species), *Parascardovia* (one species), *Scardovia* (one species), which are close phylogenetic neighbors, and the genus *Gardnerella* (one species). The phylogenetic relationships between the genera classified in the family *Bifidobacteriaceae* have been the subject of several studies (Leblond-Bourget et al., 1996; Maidak et al., 1994; Okamoto et al., 2008). A phylogenetic tree based on 16S rRNA gene sequences showing the relationships within and between the genera classified in the family *Bifidobacteriaceae* is shown in Figure 66.

Cells of members of this family consist of pleomorphic rods that occur singly or in many-celled chains or clumps. Cells do not have capsules, are nonsporeforming, nonmotile, and nonfilamentous, and are Gram-stain-positive, except for *Gardnerella vaginalis*, which is Gram-stain-variable. They are anaerobic (among the *Bifidobacterium* species, some can tolerate O_2, but only in the presence of CO_2; *Bifidobacterium psychraerophilum*, *Bifidobacterium scardovii*, and *Bifidobacterium tsurumiense* can grow under aerobic conditions) or facultatively anaerobic (*Gardnerella*). However, *Aeriscardovia* can grow under aerobic conditions. Members of the family are negative for gelatin hydrolysis, indole production, and oxidase activity, but possess fructose 6-phosphoketolase (F6PPK; EC 4.1.2.22), which cleaves fructose 6-phosphate into acetylphosphate and erythrose 4-phosphate. The DNA G+C content varies from 42 to 67 mol%. They are chemo-organotrophs, having a fermentative type of metabolism, and produce acid, but not gas, from a variety of carbohydrates. Optimum growth temperature is 30–39°C.

Members of the family have been isolated from animal and human sources. They are non-pathogenic except for *Bifidobacterium dentium*, *Scardovia inopinata*, and *Parascardovia denticolens*, which have been isolated from dental caries and are probably involved in caries pathology. *Gardnerella vaginalis* often assumes pathogenic characteristics, such as in bacterial vaginosis and in urogenital tract infections of both sexes.

DNA G+C content (mol%): 42–67 (T_m).

Type genus: **Bifidobacterium** Orla-Jensen 1924, 472[AL].

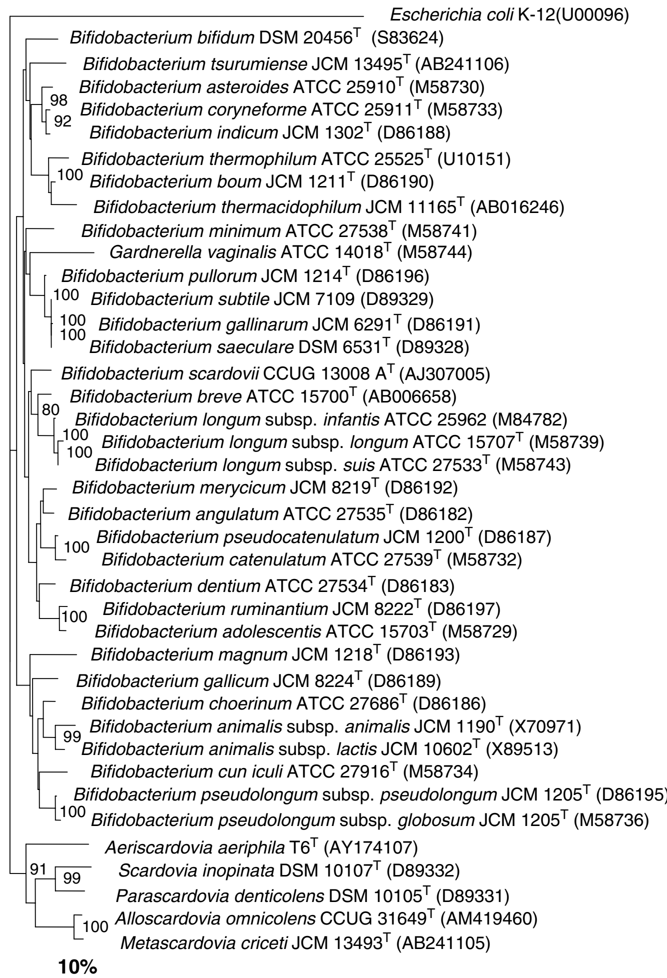

FIGURE 66. Phylogenetic tree constructed from partial 16S rRNA gene sequences of members of the family *Bifidobacteriaceae*. The tree was rooted with *Escherichia coli*, and constructed by using the neighbor-joining method with bootstrap values calculated from 1000 trees (represented as percentages and given at each branch). For each species, the GenBank accession number for the respective 16S rRNA gene sequence is indicated. The scale bar shows the number of nucleotide substitutions per site. This figure was kindly provided by Professor Maasaki Okamoto (University of Tsurumi, Japan).

Genus I. **Bifidobacterium** Orla-Jensen 1924, 472[AL]

Bruno Biavati and Paola Mattarelli

Bi.fi.do.bac.te′ri.um. L. adj. *bifidus* cleft, divided; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Bifidobacterium* a cleft rodlet.

Rods of various shapes: short, regular, thin cells with pointed ends, coccoidal regular cells, or long cells with slight bends or protuberances or with a large variety of branching; pointed, with slightly bifurcated **club-shaped or spatulated extremities**; may occur singly or in chains of many elements; may occur in star-like aggregates or in "V" or "palisade" arrangements.

Colonies are smooth, convex with entire edges, cream to white, glistening, and of soft consistency. **Gram-stain-positive, non-acid-fast, nonsporeforming, and nonmotile. Cells often stain irregularly with methylene blue**. **Anaerobic**; some species can tolerate O_2, but only in the presence of CO_2 and the more recently described species, such as *Bifidobacterium psychraerophilum*, *Bifidobacterium scardovii*, and *Bifidobacterium tsurumiense*, can grow under aerobic conditions (Okamoto et al., 2008). Optimum growth temperature is 37–41°C, except for *Bifidobacterium mongoliense*, which exhibits an optimal growth temperature of 30°C; minimum growth temperature is 25–28°C, with the exception of *Bifidobacterium mongoliense* and *Bifidobacterium psychraerophilum*, which can grow at 15°C and 8°C, respectively; maximum growth temperature is 43–45°C, with the exception of *Bifidobacterium thermacidophilum*, which exhibits a maximal growth temperature of 49.5°C. Growth at 45°C seems to discriminate between animal and human strains, since most of the animal but not the human strains are able to grow at this temperature (Gavini et al., 1991). Optimum pH for initial growth is 6.5–7.0; does not grow at pH 4.5–5.0 (except for *Bifidobacterium thermacidophilum*, which can grow at pH 4.5) or pH 8.0–8.5.

Saccharoclastic. Acetic and lactic acid are formed primarily in a 3:2 molar ratio. CO_2 is not produced (except during the degradation of gluconate). Small amounts of ethanol, formic acid, and succinic acid are produced. **Butyric and propionic acids are not produced. Glucose is degraded exclusively and characteristically by the fructose 6-phosphate shunt in which fructose-6-phosphoketolase** (F6PPK; EC 4.1.2.22) **cleaves fructose 6-phosphate into acetylphosphate and erythrose 4-phosphate.** End products are formed through the sequential action of transaldolase (EC 2.2.1.2), transketolase (EC 2.2.1.1), xylulose-5-phosphate phosphoketolase (EC 4.1.2.9) and enzymes of the Embden–Meyerhof pathway (EMP) acting on glyceraldehyde 3-phosphate. Additional acetic and formic acids may be formed through cleavage of pyruvate. Glucose-6-phosphate dehydrogenase (G6PDH; EC 1.1.1.49, $NADP^+$- or NAD^+-dependent) activity is not generally measurable.

Catalase-negative except for *Bifidobacterium asteroides* and *Bifidobacterium indicum*, which are catalase-positive when grown in the presence of air with or without added hemin. Ammonium is generally utilized as a source of nitrogen.

Source: present in the intestine of man, various animals, and honey bees. Also found in sewage, fermented milk products, and human clinical samples.

DNA G+C content (mol%): 47–67 (Bd or T_m).

Type species: **Bifidobacterium bifidum** (Tissier 1900) Orla-Jensen 1924, 472[AL] (*Bacillus bifidus* Tissier 1900, 86).

Further descriptive information

Phylogeny. Tissier discovered bifidobacteria in infant feces and called them "*Bacillus bifidus*" (Tissier, 1900, 1899). In 1924, Orla-Jensen recognized the existence of the genus *Bifidobacterium* as a separate taxon, but given their similarities to the genus *Lactobacillus*, bifidobacteria were included in the genus *Lactobacillus* as listed in the 7th edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957).

In the 8th edition of *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974), bifidobacteria were classified in the genus *Bifidobacterium*, the name initially adopted by Orla-Jensen. The genus comprised eight species and was included in the family *Actinomycetaceae* of the order *Actinomycetales*, although with regard to the murein structure of the cell wall, bifidobacteria are more similar to the family *Lactobacillaceae* than to the family *Actinomycetaceae* (Kandler and Lauer, 1974).

In the 1st edition of *Bergey's Manual of Systematic Bacteriology* (Sneath et al., 1986), as well as the 9th edition of *Bergey's Manual of Determinative Bacteriology* (Holt et al., 1993), members of the genus *Bifidobacterium* were grouped and defined as "irregular, nonsporing, Gram-positive rods".

The introduction of rRNA gene sequence analyses in studies of bacterial phylogeny confirmed the assignment of bifidobacteria to an "*Actinomyces*" group (Fox et al., 1980). rRNA gene sequence analyses were used mainly to determine relationships between genera, families, and other ranks. Molecular phylogeny, based on high correlations between several molecules, e.g., 16S rRNA genes (Woese, 1987), 23S rRNA genes (Collins and Wallbanks, 1992), and genes encoding elongation factors involved in translation and the subunit of ATPase (Ludwig et al., 1993), led to the description of domains for the three highest taxa: *Archaea*, *Bacteria*, and *Eukarya* (Woese et al., 1990).

Stackebrandt et al. (1997) proposed a novel hierarchical structure for the phylogenetic group of "*Actinomycetes*, bacteria and relatives" based on 16S rRNA gene sequence data. This proposal did not change the descriptions of species and genera based upon morphological, chemotaxonomic, and physiological properties, but provided descriptions of taxa above the genus level. The genus *Bifidobacterium* was classified as a single taxon in the family *Bifidobacteriaceae* of the order *Bifidobacteriales*, subclass *Actinobacteridae*, in the class *Actinobacteria*, phylum *Firmicutes* of the domain *Bacteria* (Stackebrandt et al., 1997). Garrity and Holt (2001), based on an extensive principal component analysis of 16S rRNA gene sequence data, proposed elevating the class *Actinobacteria* (Stackebrandt et al., 1997) to the rank of phylum, recognizing that the phylogenetic depth represented in this lineage is equivalent to that of existing phyla and that the group shows clear separation from the *Firmicutes*. Within the phylum *Actinobacteria*, the single class *Actinobacteria* was preserved as in the complete hierarchical structure proposed by Stackebrandt et al. (1997). The order *Bifidobacteriales* is classified in subclass *Actinobacteridae*, class *Actinobacteria*, phylum *Actinobacteria* in the domain *Bacteria*. The *Bifidobacteriales* comprise a separate group lying adjacent to, but away from the major lineages within the order *Actinomycetales*, a classification consistent with the published phylogenetic model of Stackebrandt et al. (1997). A 16S rRNA gene sequence-based phylogenetic tree of the family *Bifidobacteriaceae* is shown in Figure 66.

Cell morphology. Cell morphology and its variations, which are affected by different culture conditions, have been investigated widely (Poupard et al., 1973). However, recent discoveries of novel *Bifidobacterium* species from a variety of sources have permitted a clearer picture of the morphology of members of the genus. A comparison of the cell morphology of large numbers of strains grown anaerobically (Merck system) in stabs of trypticase-phytone-yeast extract (TPY) medium showed that some species had distinct cell shapes or arrangements, which might help in their identification. These traits are exemplified in Figure 67.

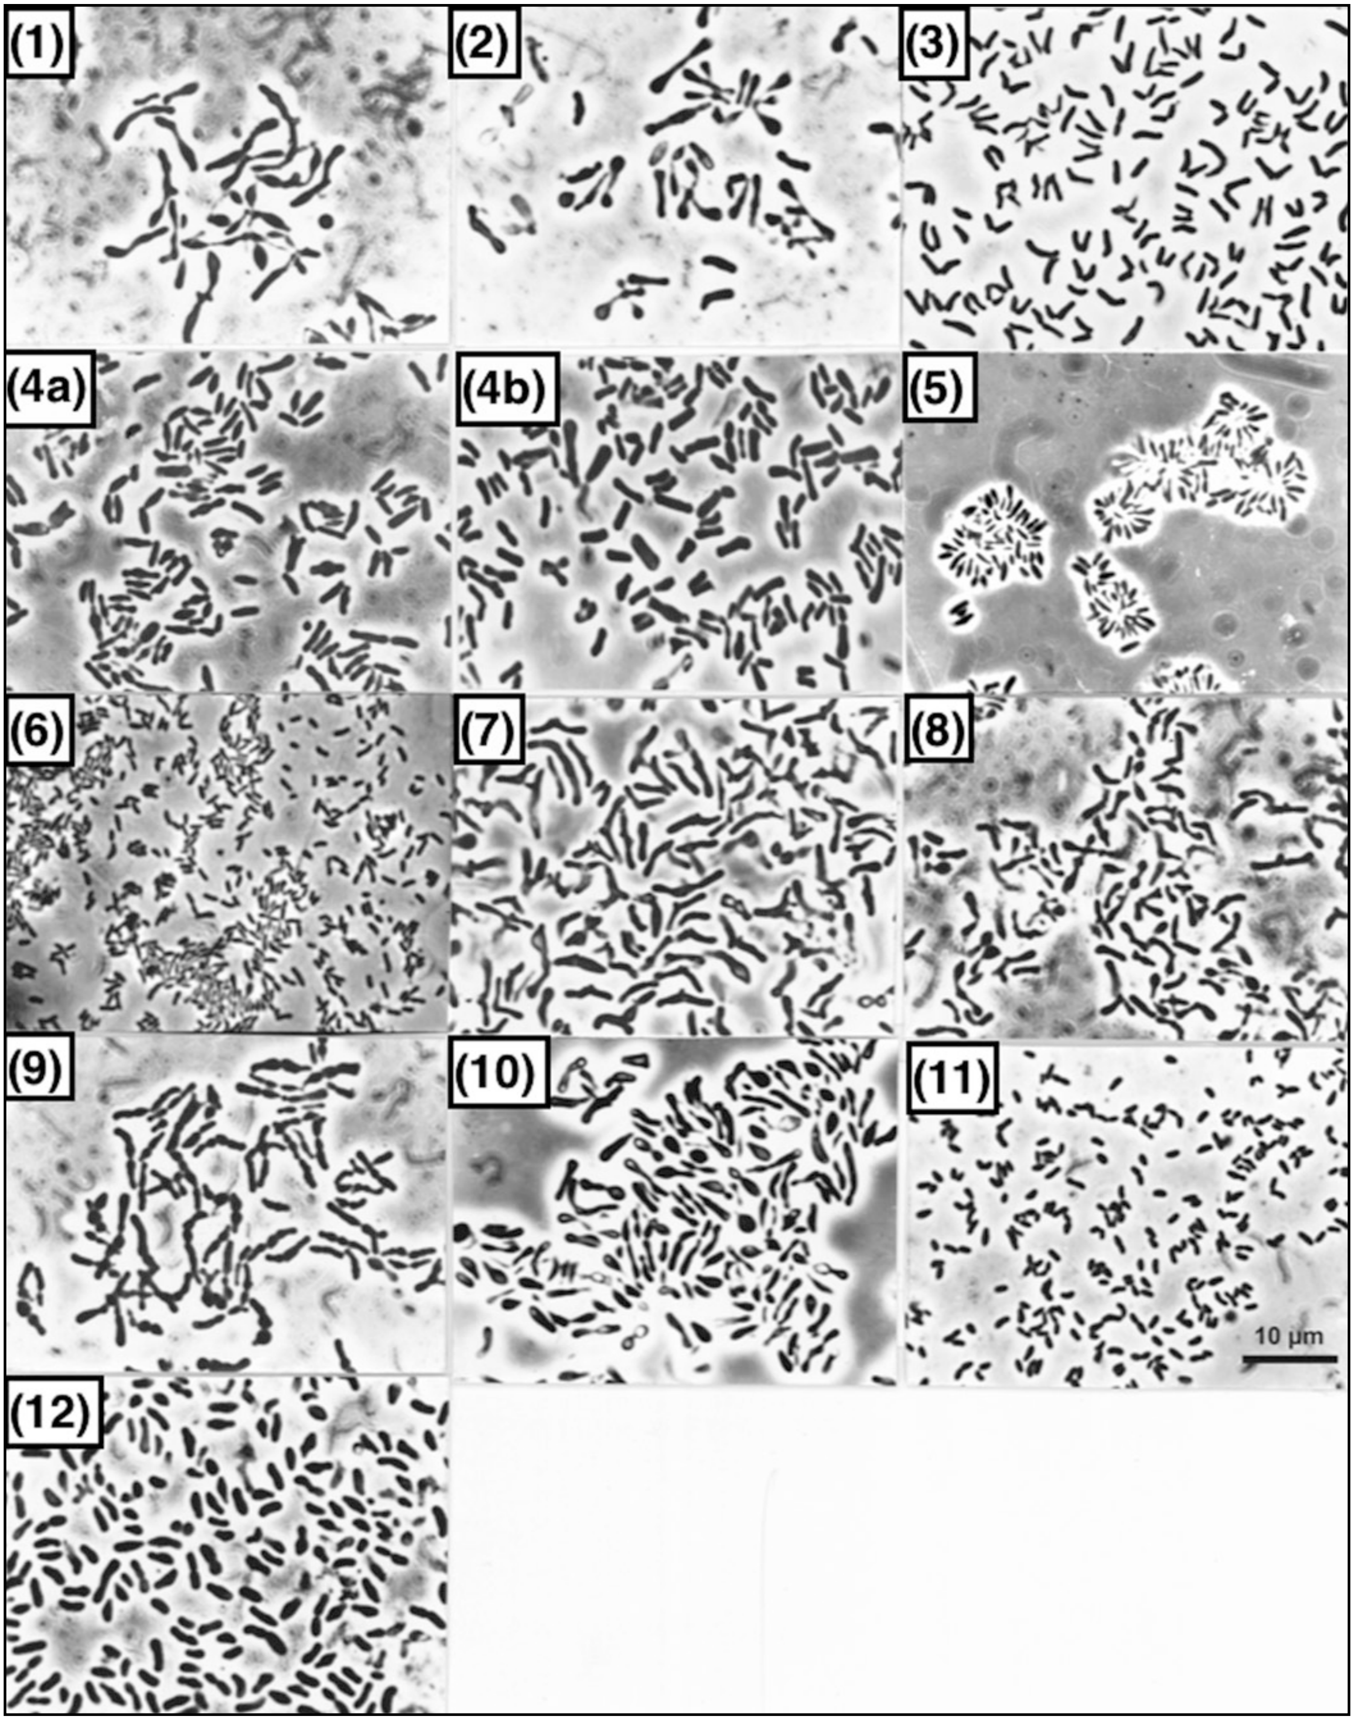

FIGURE 67 (A). (continued)

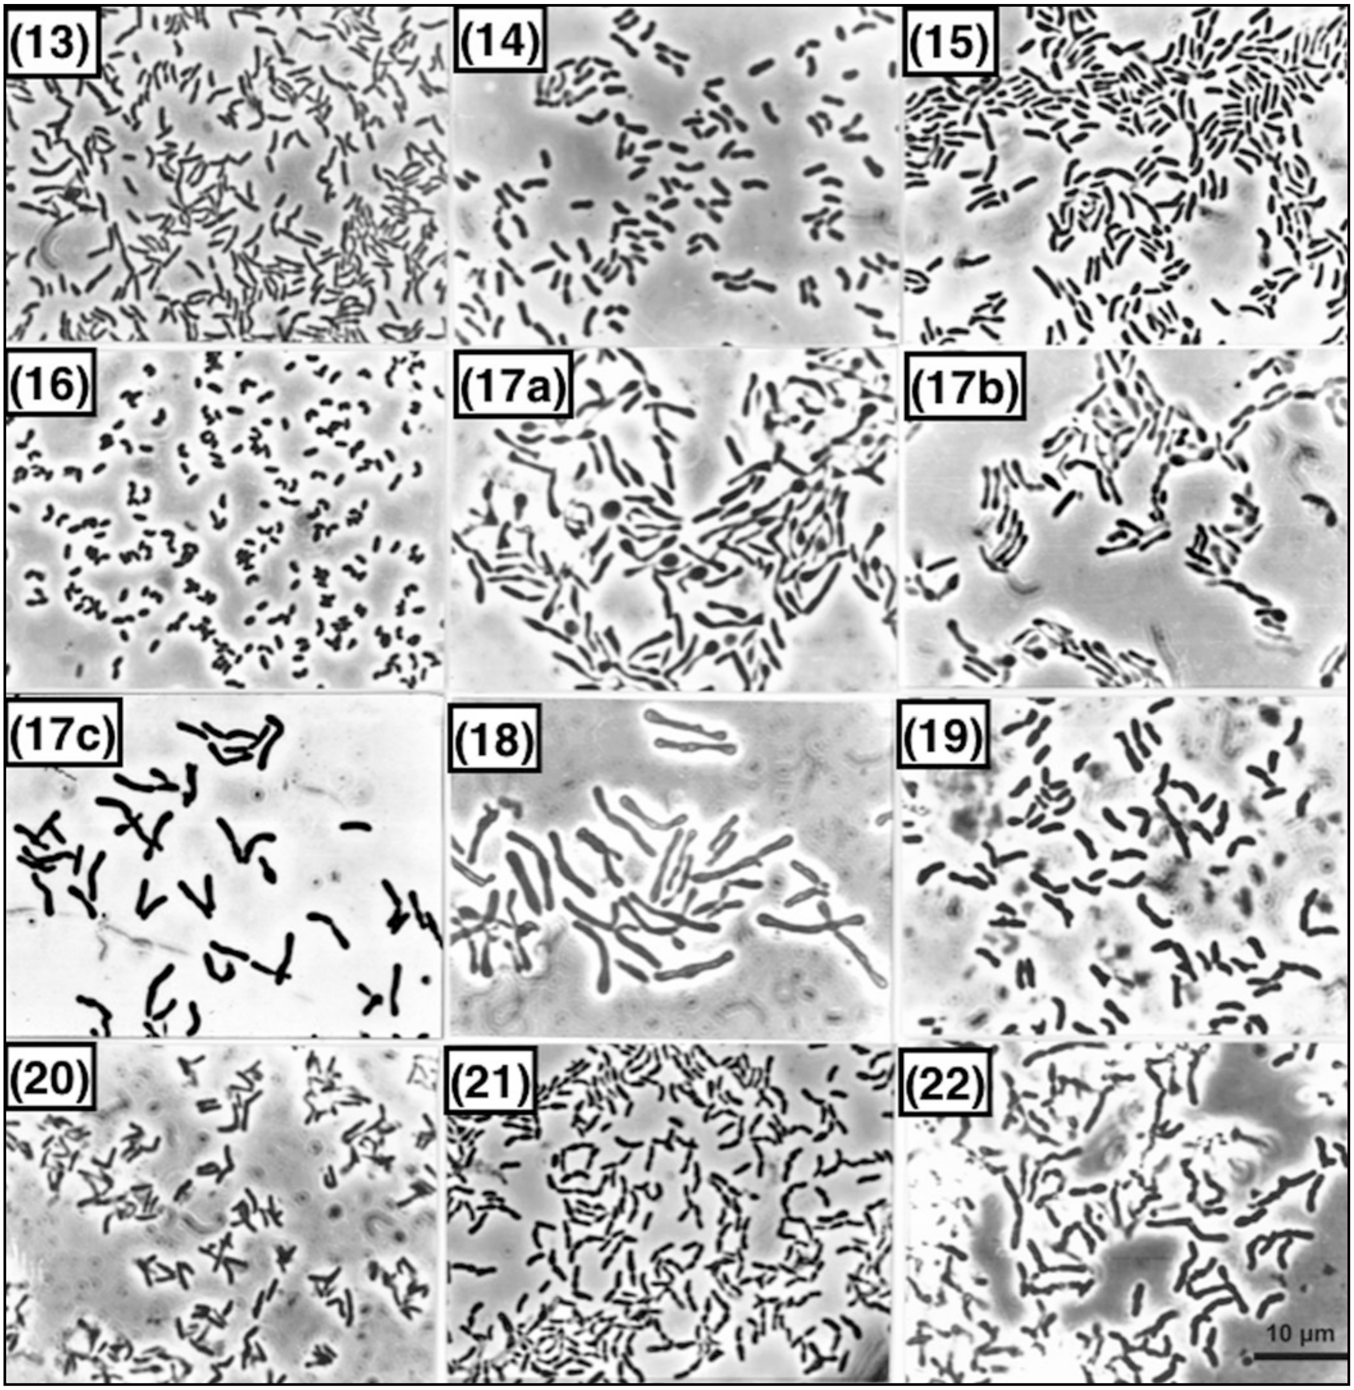

FIGURE 67 (B). (continued)

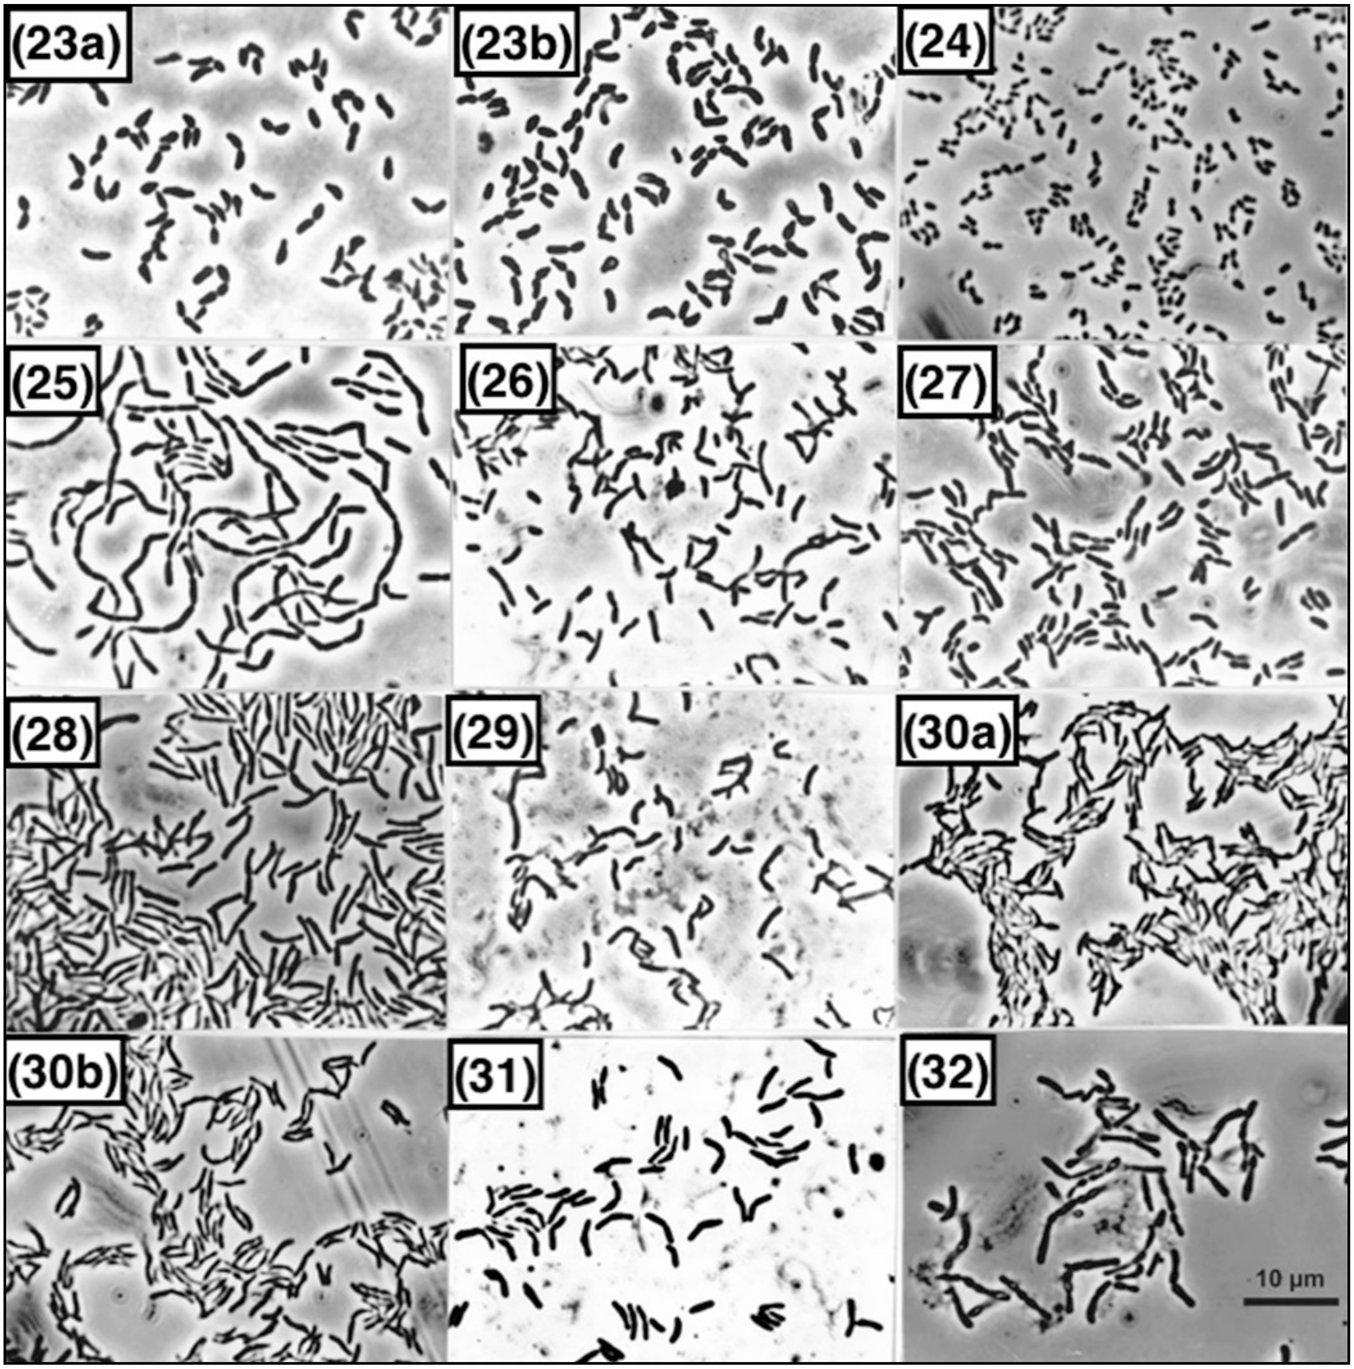

FIGURE 67 (C). (A) Panels 1–12; (B) panels 13–22; (C) panels 23–32 (panel numbers correspond to the species number in the List of species). Cellular morphology in the genus *Bifidobacterium*. Cells of the type strains were grown in TPY medium stabs. Phase-contrast photomicrographs (magnification 1500×). Part A: 1, *B. bifidum*; 2, *B. adolescentis*; 3, *B. angulatum*; 4a, *B. animalis* subsp. *animalis*; 4b, *B. animalis* subsp. *lactis*; 5, *B. asteroides*; 6, *B. bombi*; 7, *B. boum*; 8, *B. breve*; 9, *B. catenulatum*; 10, *B. choerinum*; 11, *B. coryneforme*; 12; *B. cuniculi*. Part B: 13, *B. dentium*; 14, *B. gallicum*; 15, *B. gallinarum*; 16, *B. indicum*; 17a, *B. longum* subsp. *longum*; 17b, *B. longum* subsp. *infantis*; 17c, *B. longum* subsp. *suis*; 18, *B. magnum*; 19, *B. merycicum*; 20, *B. minimum*; 21, *B. mongoliense*; 22, *B. pseudocatenulatum*. Part C: 23a, *B. pseudolongum* subsp. *pseudolongum*; 23b, *B. pseudolongum* subsp. *globosum*; 24, *B. psychraerophilum*; 25, *B. pullorum*; 26, *B. ruminantium*; 27, *B. saeculare*; 28, *B. scardovii*; 29, *B. subtile*; 30a, *B. thermacidophilum* subsp. *thermacidophilum*; 30b, *B. thermacidophilum* subsp. *porcinum*; 31, *B. thermophilum*; 32, *B. tsurumiense*.

Of particular interest are the well known amphora-like cells of *Bifidobacterium bifidum* (Sundman et al., 1959) (Figure 67, panel 1), the V or palisade arrangement of cells in *Bifidobacterium angulatum* (Figure 67, panel 3), the linear groups of globular elements in *Bifidobacterium catenulatum* (Figure 67, panel 9), the long chains of regular cells in *Bifidobacterium pullorum* (Figure 67, panel 25), the middle-enlarged cells of *Bifidobacterium animalis* (Figure 67, panels 4a and 4b), the cellular dimensions of *Bifidobacterium magnum* (Figure 67, panel 18), the small cells of *Bifidobacterium minimum* (Figure 67, panel 20) and *Bifidobacterium psychraerophilum* (Figure 67, panel 24), and the unusual star-like arrangements of cells of *Bifidobacterium asteroides* (Figure 67, panel 5).

The cellular shape most frequently encountered in *Bifidobacterium* species that do not have a distinct morphology as observed on TPY stabs (see above) is depicted in Figure 67, panel 26. Details of cellular morphologies are given under single species descriptions. *Bifidobacterium asteroides* (star-like clusters) and *Bifidobacterium indicum* (small rods or coccobacilli), the species with the most nonbifid-like morphology in the classic sense, show features that are common to the morphology of the other bifidobacteria only when grown in nutritionally deficient media (Scardovi and Trovatelli, 1969); this seems to be a general trend in this group of bacteria (Glick et al., 1960; Sundman and Björksten, 1958).

Cell-wall composition. Several workers have studied the cell-wall murein structure of bifidobacteria (Kandler and Lauer, 1974; Lauer and Kandler, 1983) (Table 21). Closely related species can be distinguished clearly on this basis, for example, *Bifidobacterium boum* from *Bifidobacterium thermophilum*, and *Bifidobacterium minimum* from *Bifidobacterium subtile*. These authors also reported that bifidobacterial cell walls contained significant amounts of polysaccharides, normally galactose and glucose often associated with rhamnose. The structure and composition of cell-wall polysaccharides have been investigated (Habu et al., 1987; Nagaoka et al., 1988, 1995). The presence of lipoteichoic acid, which remains insoluble after lysozyme treatment, in the cell wall has been reported in *Bifidobacterium bifidum* (Veerkamp et al., 1983); its chemical composition and structure have been studied (Fischer et al., 1987; Op den Camp et al., 1984). Immunochemical studies have indicated that lipoteichoic acid is a common antigen within the genus *Bifidobacterium* (Op Den Camp et al., 1985b). Furthermore, proteins and lipoteichoic acid are responsible, either independently or in dynamic complexes, for the hydrophobic character of the bifidobacterial surface (Op den Camp et al., 1985a).

Mukai et al. (1997) suggested that cell surface proteinaceous components are involved in the adhesion of *Bifidobacterium adolescentis*. Studies on cellular structures (lipoteichoic acids, proteins) and the interaction of cells with substrates (*in vivo* and *in vitro* adhesion) are needed to understand the mechanisms that regulate bacterial adhesion and, therefore, colonization. Protein ligands present on the cell surfaces and/or in the culture medium have been identified by Bernet et al. (1993) in some strains of bifidobacteria of human origin (*Bifidobacterium bifidum*, *Bifidobacterium breve*, *Bifidobacterium longum* subsp. *infantis*, and *Bifidobacterium longum* subsp. *longum*). These investigations have shown that different strains belonging to the same species adhere differently to intestinal cells of Caco-2 and HT29MTX cell lines. More recently, Pérez et al. (1998) studied the adhesive capacity of some strains of human origin showing that, in many cases, adhesion was linked to the self-agglutination capacity of such strains: organisms with a high self-agglutination capacity tested positive by hemagglutination and showed a high surface hydrophobicity.

An important contribution to the study of cell-wall-associated proteins in *Bifidobacterium pseudolongum* subsp. *globosum* was made by Mattarelli et al. (1993). Using plasmid-free clones, obtained by "curing", the involvement of certain plasmids in determining the surface protein patterns was ascertained. Sensitivity to lytic and bactericidal activities of lysozyme and cationic polypeptides was found to be related to the presence of a plasmid-dependent surface protein of high molecular mass (Mattarelli et al., 1997). The effect of temperature on the biosynthesis of cell-wall proteins and cell hydrophobicity has been studied in *Bifidobacterium pseudolongum* subsp. *globosum*. The production of cell-wall proteins is temperature-dependent: expression at low temperature is considerably attenuated, whereas it increases at medium and high growth temperatures. At medium growth temperatures, cell hydrophobicity was strictly correlated with cell-wall protein expression, whereas at low and high growth temperatures, the presence of cell-wall protein only partially influenced the hydrophobic features (Mattarelli et al., 1999).

The relationship between interaction sites in the gut, hydrophobicity, mucosal immunomodulating capacities, and cell-wall protein profiles in bifidobacteria was investigated by Vinderola et al. (2004). The differences in the immunopotentiating capacity of the various strains might be related to differences in their cell-wall protein profiles. The relationship between the presence of cell-wall proteins and autoaggregating ability in *Bifidobacterium adolescentis* and *Bifidobacterium bifidum* was investigated by Canzi et al. (2005). These authors also characterized the cell surface properties of *Bifidobacterium* strains isolated from human fecal material.

A deeper understanding of the ecological variability of the surface structure in members of the genus *Bifidobacterium* and its function in the multifaceted relationships of host and bacterium are thought to be important prerequisites for a better understanding of the colonization mechanism of bifidobacteria.

The phospholipid composition of some *Bifidobacterium* and *Lactobacillus* species were studied by Exterkate et al. (1971). Differences in polyglycerol phospholipid and aminoacyl phosphatidylglycerol composition helped to differentiate between the two genera. The effects of growth conditions on the lipid and ionic composition of *Bifidobacterium bifidum* were examined by Veerkamp (1977a, 1977b). The changes in bacterial lipid surface composition during growth in bile-containing medium were studied by Gómez Zavaglia et al. (2002), who found that lipid composition was not directly related to adhesive properties.

Fine structure. The ultrastructure of bifidobacteria has received little attention. Overman and Pine (1963) presented ultrastructure micrographs of *Bifidobacterium bifidum* (strain Reuter, S 28a variant, ATCC 15696). Zani and Severi (1982) made a more extensive investigation of the ultrastructure of this strain. Scanning and transmission electron microscopy studies revealed a possible sequence of morphological events during transformation from one pleomorphic form to another in

Bifidobacterium bifidum and *Bifidobacterium longum* subsp. *longum* (Bauer et al., 1975). An ultrastructural study of *Bifidobacterium pseudolongum* subsp. *pseudolongum* and *Bifidobacterium thermophilum* revealed the production of extensive amounts of extracellular material only in the former. The cell walls of these organisms differed in thickness: approximately 0.2 μm and approximately 0.05 μm for *Bifidobacterium pseudolongum* subsp. *pseudolongum* and *Bifidobacterium thermophilum*, respectively (Kudo et al., 1989).

Nutrition and growth conditions. Little was known about bifidobacterial nutrition up to 1969. The majority of studies focused on *Bifidobacterium bifidum* (strain Gyorgy and Rose 212A, ATCC 11863, *ex Lactobacillus bifidus* var. *pennsylvanicus*). Some of these studies demonstrated that biotin and calcium pantothenate, in association with cysteine, were essential components for growth promotion and that calcium pantothenate could be replaced by pantethine (Hassinen et al., 1951). This strain was found to require pantethine, a "bifidus factor" oligosaccharide-type compound present in human milk and a "supplementary factor" present in human and cow's milk and in pancreatic extract (György and Rose, 1955). The growth stimulating effect of pancreatin had previously been shown by Tomarelli et al. (1949).

In 1969, Scardovi and Trovatelli showed that only *p*-aminobenzoic and folic acids, together with their bases, were indispensable for the growth of *Bifidobacterium asteroides*, a species isolated from honey bees, when it was cultivated on synthetic medium (Gyllenberg and Carlberg, 1958). Later, a survey on the nutritional requirements of nine *Bifidobacterium* species of human and animal origin, including *Bifidobacterium dentium*, demonstrated greater heterogeneity among the species, with calcium pantothenate and riboflavin being the most frequently required nutrients for growth (Trovatelli and Biavati, 1978). The results of Matteuzzi et al. (1978) from a survey of 18 *Bifidobacterium* species were in agreement with those of Hassinen et al. (1951), namely that a large number of bifidobacteria grew on ammonium salts as a sole nitrogen source in a relatively simple synthetic medium, although *Bifidobacterium choerinum*, *Bifidobacterium cuniculi*, *Bifidobacterium magnum*, *Bifidobacterium pseudolongum* subsp. *globosum*, and *Bifidobacterium longum* subsp. *suis* did not grow in the absence of organic nitrogen (Mattarelli and Biavati, 1999b). The pantothenate-type compounds biotin and riboflavin were also reported to be required for growth of human species of the genus, such as *Bifidobacterium adolescentis*, *Bifidobacterium bifidum*, *Bifidobacterium breve*, *Bifidobacterium longum* subsp. *infantis*, and *Bifidobacterium longum* subsp. *longum* (Deguchi et al., 1985). In addition, nicotinic acid and thiamin have been found to be essential for some *Bifidobacterium* strains.

The activity of enzymes such as glutamate dehydrogenase and glutamine synthetase allows the assimilation of ammonia. Glutamine synthetase has been isolated and characterized from *Bifidobacterium bifidum*, *Bifidobacterium breve*, and *Bifidobacterium pseudolongum* subsp. *pseudolongum* (Hatanaka et al., 1987).

In organic nitrogen-free media, considerable amounts of various amino acids are excreted by strains of *Bifidobacterium adolescentis*, *Bifidobacterium animalis*, *Bifidobacterium dentium*, *Bifidobacterium longum* subsp. *infantis*, and *Bifidobacterium thermophilum*. In general, the amino acids produced in the largest amounts are alanine, aspartic acid, and valine. *Bifidobacterium bifidum* can produce up to 150 mg/l threonine (Matteuzzi et al., 1978).

Analog-resistant mutants obtained from *Bifidobacterium thermophilum* (*ex Bifidobacterium ruminale*) show increased production of isoleucine and valine (Crociani et al., 1977; Matteuzzi et al., 1976). Homoserine dehydrogenase and threonine deaminase activities, as well as some aspects of their regulation, have been studied in many *Bifidobacterium* species (Selli et al., 1986).

Studies on the nutrition of plasmid-negative and plasmid-positive clones of *Bifidobacterium pseudolongum* subsp. *globosum* revealed auxotrophy for L-methionine in both clones (Mattarelli and Biavati, 1999b). Auxotrophy for L-leucine was shown only for plasmid-positive clones, thereby showing the involvement of plasmids in this requirement. The lack of β-isopropyl malate dehydrogenase enzyme activity is considered to be responsible for the L-leucine auxotrophy in the plasmid-positive clones. Minimal amino acid requirements were also investigated. Only six or seven amino acids were required for growth, regardless of the ones chosen, including L-leucine and/or L-methionine for plasmid-positive and plasmid-negative clones, respectively (Mattarelli and Biavati, 1999a).

A survey of growth factor and vitamin requirements was made in 10 species of bifidobacteria and the different species were shown to have a great deal of heterogeneity. Comparative studies on the synthesis of water-soluble vitamins (cyanocobalamin, folic acid, nicotinic acid, pyridoxine, riboflavin, and thiamin) among species isolated from human feces have shown that many strains can synthesize all of the vitamins tested, with the exception of pantothenic acid and riboflavin (Tamura, 1983; Trovatelli and Biavati, 1978). The concentration of the vitamins accumulated varies widely among different species or strains (Deguchi et al., 1985). The ability of bifidobacteria to synthesize biotin has also been demonstrated (Noda et al., 1994).

Some factors, called "bifidus factors", are able to stimulate growth of bifidobacteria. The first "bifidus factor" was proposed by György et al. (1954a, 1954b); it has been found in human milk and also, in minor amounts, in the milk of several other mammals. This factor was later found to be composed of glycoproteins and oligosaccharides containing *N*-acetyl-D-glucosamine (Bezkorovainy and Topouzian, 1981). Another bifidogenous factor has been identified in the low protein content of human milk. A reduction in the protein content of milk formulae should lower the buffering capacity and thus allow the formation of an acidic milieu in the gut that can promote the growth of bifidobacteria (Heine et al., 1992). However, in an experimental study, the use of protein-reduced formula milk (1.2 g/100 ml) did not increase the number of bifidobacteria.

Lactoferrin, an iron-binding protein, promotes the growth of bifidobacteria. The study by Petschow et al. (1999) suggested that bovine lactoferrin from mature milk increases the growth of *Bifidobacterium breve* and *Bifidobacterium infantis* in a concentration-dependent way *in vitro*, whereas human lactoferrin promotes the growth of *Bifidobacterium bifidum*, but not that of *Bifidobacterium breve* and *Bifidobacterium infantis*. Oligo- and polysaccharides are also classified as "bifidogenic factors"; this may be explained by the evolution of these bacteria in the gastrointestinal tract where competition for nutrients is intense.

Pure culture growth studies have shown that, in addition to a wide spectrum of suitable energy sources, bifidobacteria show

TABLE 21. Type strains, chemotaxonomic properties, and sources of species of the genus *Bifidobacterium*

Species	Murein type[a]	DNA G+C content[b]	Electrophoretic patterns of enzymes:[c] 6PGD	Transaldolase	Source
B. bifidum	L-Orn–D-Ser–D-Asp	61	**7**, (8)	7	Feces of human adults, infants, and suckling calves; human vagina
B. adolescentis	L-Lys(L-Orn)–D-Asp	59	5	8	Feces of human adults; bovine rumen; sewage
B. angulatum	L-Lys–D-Asp	59	5	5	Sewage; feces of human adult
B. animalis					
subsp. *animalis*	L-Lys(L-Orn)–L-Ser–(L-Ala)–L-Ala_2	61.3	8, **9**	5	Feces of guinea pigs and rats
subsp. *lactis*	L-Lys(L-Orn)–L-Ser–(L-Ala)–L-Ala_2	61	nt	nt	Feces of calves, chickens, and rabbits; sewage; fermented milk (yogurt)
B. asteroides	L-Lys–Gly	59	(9), (9a), (9b), (10), **10a**, 10b, (11), (12), (13)	(6), (7), (7a), **8**, (8a), (8b), (9), (9a)	Intestine of *Apis mellifera* subsp. *caucasica*, *ligustica*, and *mellifera*
B. bombi		47.3	nt	nt	Digestive tract of different bumblebees
B. boum	L-Lys–D-Ser–D-Glu	60	**8**, 9, 9a	6	Bovine rumen; feces of piglets
B. breve	L-Lys–Gly	58 (Bd)	(5), 6, 6a, 7	6	Feces of infants and suckling calves; human vagina; sewage
B. catenulatum	L-Lys(L-Orn)–L-Ala_2–L-Ser	54.7	**6**, 8	5	Feces of infants and human adults; human vagina; sewage
B. choerinum	L-Lys(L-Orn)–L-Ser–(L-Ala)–L-Ala_2	66.3	4	3	Feces of piglets; sewage
B. coryneforme	L-Lys–D-Asp	nt	6	6	Intestine of *Apis mellifera* subsp. *mellifera*
B. cuniculi	L-Lys(L-Orn)–L-Ser–(L-Ala)–L-Ala_2	64.1	4	1	Feces of rabbits
B. dentium	L-Lys(L-Orn)–D-Asp	61.2	(2)	4	Human dental caries and oral cavity; feces of human adults; human vagina; human abscess and appendix
B. gallicum	L-Lys–L-Ala–L-Ser	61	nt	Present	Human feces
B. gallinarum	L-Lys–D-Asp	65.7	Absent	Present	Chicken cecum
B. indicum	L-Lys–D-Asp	60	6, 6a, (7), 8, (**9**), (9a), (9b)	(6), 7, 8, **9**	Intestine of *Apis cerana* and *A. dorsata*
B. longum					
subsp. *longum*	L-Orn–L-Ser–L-Ala–L-Thr–L-Ala	61	5, (**6**)	(5), 6, **8**	Feces of human adults, infants, and suckling calves; human vagina; sewage
subsp. *infantis*	L-Orn–L-Ser–L-Ala–L-Thr–L-Ala	60.5	(3), **4**, (5)	5, (6), (**8**)	Feces of infants and suckling calves; human vagina
subsp. *suis*	L-Orn–L-Ser–L-Ala–L-Thr–L-Ala	62	5, 8	6	Feces of piglets
B. magnum	L-Lys(L-Orn)–L-Ala_2–L-Ser	60	7	5	Feces of rabbits
B. merycicum	L-Lys(L-Orn)–D-Asp	59	Present	Present	Bovine rumen
B. minimum	L-Lys–L-Ser	61.5	6	10	Sewage; pig cecum
B. mongoliense	L-Lys–D-Asp	61.1	nt	nt	Fermented milk (airag)
B. pseudocatenulatum	L-Lys(L-Orn)–L-Ala_2–L-Ser	57.5	**1**, 3	**4**, (5)	Feces of infants and suckling calves; sewage

B. pseudolongum					
subsp. *pseudolongum*	L-Orn(L-Lys)–L-Ala_{2-3}	64.8	(**3a**), (4), (5), (**6**), (7)	2	Feces of bulls, calves, chickens, dogs, guinea pigs, pigs, and rats
subsp. *globosum*	L-Orn(L-Lys)–L-Ala_{2-3}	64.1	7	2	Bovine rumen; feces of lambs, piglets, rabbits, rats, and suckling calves; sewage
B. psychraerophilum		59.2	nt	nt	Pig cecum (content and epithelium)
B. pullorum	L-Lys–D-Asp	67.4	nd	2	Feces of chickens
B. ruminantium	L-Lys(L-Orn)–L-Ser–(L-Ala)–L-Ala_2	57	Present	Present	Bovine rumen
B. saeculare	L-Lys(L-Orn)–D-Asp	63	Absent	Present	Feces of rabbit
B. scardovii	L-Lys–L-Ser–L-Ala	60 (HPLC)	nt	nt	Human blood
B. subtile	L-Lys–D-Asp	61.5	2	3	Sewage
B. thermacidophilum					
subsp. *thermacidophilum*		56.8	nt	nt	Wastewater
subsp. *porcinum*		61	nt	nt	Piglet feces
B. thermophilum	L-Orn(L-Lys)–D-Glu	60	7, 8, **9**, (9a)	(7), **8**	Feces of chickens, pigs, and suckling calves; bovine rumen; sewage
B. tsurumiense	Glu–Lys–Asp–$(Ala)_2$	53	nt	nt	Hamster dental plaque

[a] Data from Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (DSMZ). Amino acids given in parentheses partly replace the other one cited.

[b] Mean values (mol%) are given; data from Scardovi (1986). For data for recently described species, see species descriptions.

[c] Numbers 1–13 and 1–10 were given to 6-phospho-D-gluconate dehydrogenase isoenzymes:NAD(P)oxidoreductase (6PGD) and transaldolase, respectively, based on the order of decreasing mobility ("a" and "b" indicate additional isozymes). Numbers in bold are the isozymes of the type strains. Numbers in parentheses are isozymes found in less than 10% of the strains studied. 6PGD is undetectable by spot staining in most strains of *Bifidobacterium dentium* and in all strains of *Bifidobacterium pullorum*. "Present" and "Absent" indicate the presence and absence, as determined by other methods. Data from Scardovi et al. (1979a). nt, Not tested; nd, not detectable.

preferences for different molecules. Substrate utilization shows growth rates with considerable interspecies and interstrain differences (Gibson and Wang, 1994b; Hopkins et al., 1998). Furthermore, it has also been found that oligomeric forms of some monosaccharides are utilized more efficiently than the monomer itself (Anderson et al., 2001). Among the numerous oligosaccharides, soybean oligosaccharides, which consist mainly of the trisaccharide raffinose and the tetrasaccharide stachyose (Benno et al., 1987; Hayakawa et al., 1990; Yazawa et al., 1978), stimulate growth of bifidobacteria. More recently, other oligosaccharides have been identified and termed "bifidogenic factors", such as fructooligosaccharides (FOS) (Gibson and Wang, 1994a; Roberfroid et al., 1998), synthetic oligosaccharides, and transgalactosylated oligosaccharides (TOS) (Bouhnik et al., 1997; Ito et al., 1993). Glucooligosaccharides also stimulate the growth of bifidobacteria, although less intensely than FOS and TOS (Djouzi and Andrieux, 1997; Jaskari et al., 1998). The polysaccharide inulin also increases fecal bifidobacteria, having a similar prebiotic effect to oligofructose (Gibson and Roberfroid, 1995). In conclusion, "bifidogenic factors" can be classified into two large groups: oligosaccharides and protein hydrolyzates. In recent years, the need for bifidus factors for growth has been questioned because it is possible to obtain bifidobacterial multiplication in the absence of these factors and, hence, they cannot be defined as growth factors.

The metalloelement requirements of *Bifidobacterium bifidum* and *Bifidobacterium thermophilum* have been studied extensively by Bezkorovainy and colleagues (Bezkorovainy and Topouzian, 1983; Bezkorovainy et al., 1986, 1987; Topouzian et al., 1984). It is to be hoped that these investigations, which are important for bifidobacterial ecology, will be extended to other species of the genus. Bifidobacteria accumulate iron when it is presented in the ferrous oxidation state. This form of iron would be expected under anaerobic conditions, such as those prevalent in the human colon or cattle rumen. The iron accumulation by bifidobacteria under these conditions may serve a host defense function ("nutritional immunity") preventing the growth of pathogens for want of iron (Bezkorovainy and Solberg, 1989). Bifidobacteria possess a membrane-bound ferrireductase, which ensures the conversion of iron from the ferric to the ferrous state at the cell surface. In *Bifidobacterium*, iron uptake does not depend on siderophore-type carriers, but on a proton-motive-force-associated electrogenic pump or pumps (Kot and Bezkorovainy, 1993).

Anaerobiosis. Bifidobacteria are anaerobic micro-organisms. They usually do not develop in plates under aerobic conditions. However, oxygen sensitivity differs depending on the strain or species, the reasons for which are equivocal (de Vries and Stouthamer, 1969). Most species do not develop in slants incubated under an atmosphere of CO_2-enriched air (90% air/10% CO_2), but *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium thermophilum*, and *Bifidobacterium longum* subsp. *suis* do so without the cells becoming catalase-positive even if hemin is added to the medium. *Bifidobacterium asteroides* grows under these conditions and becomes catalase-positive. *Bifidobacterium indicum* behaves similarly, but is catalase-positive only if hemin is added to the medium (Matteuzzi et al., 1971; Scardovi and Trovatelli, 1969; Scardovi et al., 1969). Most of the recently described species, *Bifidobacterium mongoliense*, *Bifidobacterium psychraerophilum*, and *Bifidobacterium tsurumiense*, can grow on agar under aerobic conditions (Okamoto et al., 2008; Simpson et al., 2004; Watanabe et al., 2009).

Metabolism and metabolic pathways. The fermentation of hexose occurs in the genus *Bifidobacterium* through the sequence of reactions (bifid shunt) shown in Figure 68 (de Vries and Stouthamer, 1967; Scardovi and Trovatelli, 1965; Veerkamp, 1969a, 1969b). However, the theoretical ratio of acetate/lactate of 1.5:1.0 is scarcely ever found in growing cultures of bifidobacteria. Phosphoroclastic cleavage of some pyruvate to formic acid and acetyl phosphate and reduction of acetyl phosphate to ethanol often alters the fermentation balance in favor of the production of acetate and some formic acid and ethanol. Given X as the amount of formic acid produced, the general reaction postulated is: glucose → $(1.5 + 0.5X)$acetate + $(1.0 - X)$lactate + 0.5Xethanol + Xformate (de Vries and Stouthamer, 1968; Lauer and Kandler, 1976). G6PDH and aldolase are either considered to be absent or not detectable, thereby ruling out the monophosphate pathway and the glycolytic system (de Vries and Stouthamer, 1967), although low but detectable levels of these two enzymes have been found in some species (Scardovi and Sgorbati, 1974).

The enzymes of the Leloir pathway of galactose metabolism, i.e., galactokinase (EC 2.7.1.6), hexose-1-phosphate uridylyltransferase (EC 2.7.7.12), and UDP-galactose 4-epimerase (EC 5.1.3.2) are constitutive in glucose-grown cells of *Bifidobacterium*, whereas in other micro-organisms these enzymes are induced by either galactose or fucose (Lee et al., 1980).

The existence of UDP-galactose pyrophosphorylase (Lee et al., 1978) suggests that, at least in *Bifidobacterium* species from human sources, an alternative pathway based on galactose is operative (Lee et al., 1979).

The enzymic carboxylation of phosphoenolpyruvate to oxaloacetate in some bifidobacteria from human feces and from honey bees has been compared with the corresponding activity in strains of *Actinomyces bovis* and *Actinomyces israelii*. In bifidobacteria, this activity is independent of the phosphate acceptor and is irreversible, whereas in *Actinomyces* it is inosine- or guanosine-diphosphate-dependent (Chiappini, 1966).

Many enzymes for feeding mono- and disaccharides into the fructose 6-phosphate shunt have been identified but, in addition, arabinosidases, α- and β-galactosidases, glucosidases, hexosaminidases, inulinase, isomaltase, mannosidases, neopullanase, and xylanases are also present. In addition to those enzymes responsible for degrading complex carbohydrates, eight high-affinity oligosaccharide transporters were found and this may explain preferences for oligomerized sugars.

FOS are among the sugars that qualify as prebiotics. They comprise a diverse family of naturally occurring oligosaccharides used commercially in food products and nutritional supplements. They represent nondigestible oligosaccharides and are composed of short- to medium-size chains of fructose moieties connected by β(2–1) linkages (degree of polymerization, 4–60), which are in turn attached to a terminal glucose unit [also by a β(2–1) bond]. Because of these β(2–1) linkages, FOS are resistant to mammalian enzymes and, thus, are able to reach the colon, where they are reported to serve as a source of highly digestible substrates for bifidobacteria (Cummings et al., 1989; Gilliland, 1990; McKellar and Modler, 1989; Modler et al., 1990).

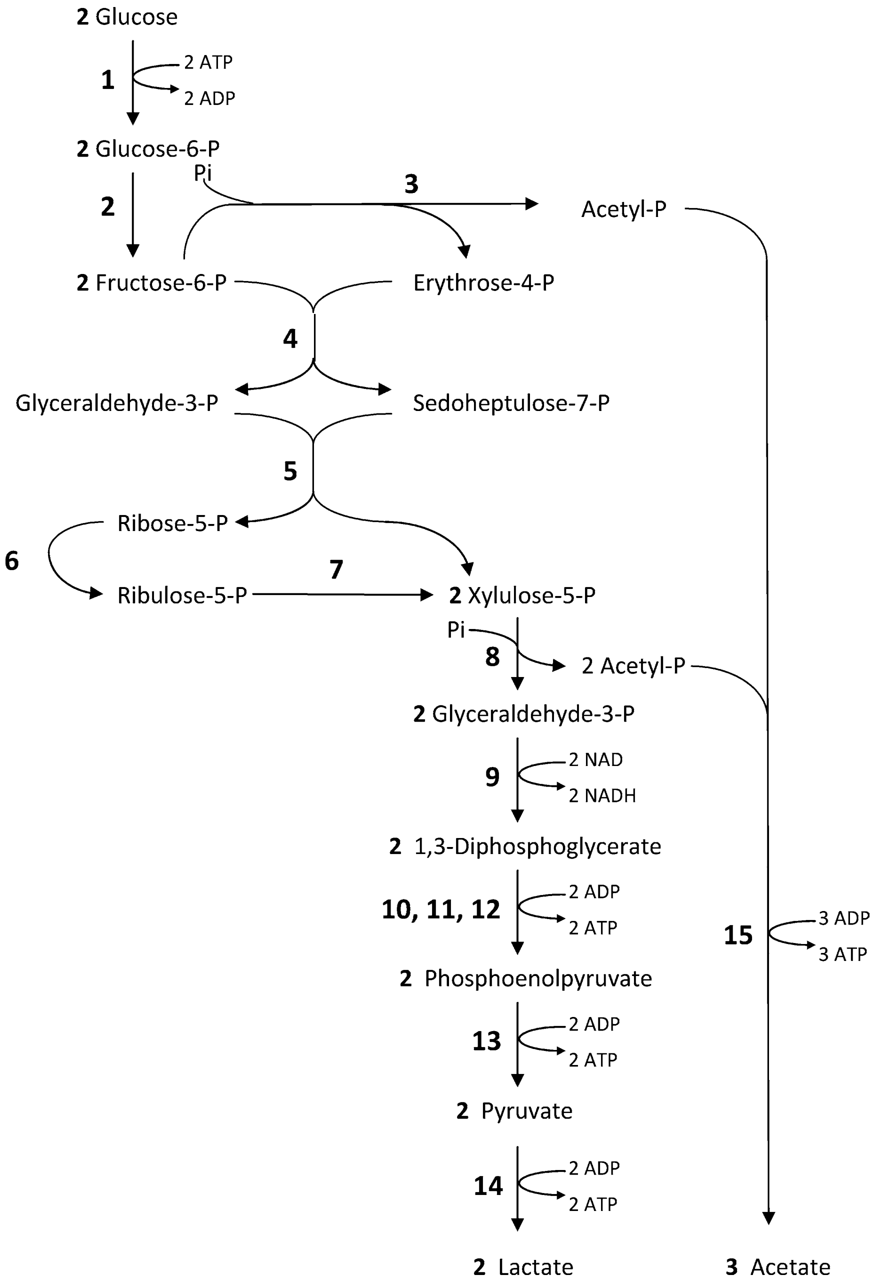

FIGURE 68. *Bifidobacterium* shunt. 1, Hexokinase (EC 2.7.1.2); 2, glucose-6-phosphate isomerase (EC 5.3.1.9); 3, fructose-6-phosphate phosphoketolase (EC 4.1.2.22); 4, transaldolase (EC 2.2.1.2); 5, transketolase (EC 2.2.1.1); 6, ribose-5-phosphate isomerase (EC 5.3.1.6); 7, ribulose-5-phosphate epimerase (EC 4.1.2.9); 8, xylulose-5-phosphate phosphoketolase (EC 4.1.2.9); 9, glyceraldehyde-3-phosphate dehydrogenase (EC 1.2.1.12); 10, phosphoglycerate kinase (EC 2.7.2.3); 11, phosphoglyceromutase (EC 5.4.2.1); 12, enolase (EC 4.2.1.11); 13, pyruvate kinase (EC 2.78.1.40); 14, lactate dehydrogenase (EC 1.1.1.27); 15, acetate kinase (EC 2.7.2.1).

Invertase (EC 3.2.1.26; β-fructofuranosidase) catalyzes hydrolysis of the β(2-1) glycosidic linkage of sucrose releasing an equimolar mixture of glucose and fructose. Recent research on invertase activities found in bifidobacteria has demonstrated that invertase breaks down FOS as well as sucrose (Ehrmann et al., 2003; Imamura et al., 1994; Janer et al., 2004; McKellar and Modler, 1989; Muramatsu et al., 1992; Warchol et al., 2002). An exoinulinase that exhibits β-fructofuranosidase activity has been purified from *Bifidobacterium infantis* ATCC 15697[T]. This enzyme was a monomeric protein (M_r of 70,000) that catalyzes the degradation of both sucrose and inulin (Warchol et al., 2002). A β-fructofuranosidase identified from *Bifidobacterium infantis* was shown to be composed of three identical subunits (M_r of 75,000) and to be capable of catalyzing the hydrolysis of inulin, 1-kestose, nystose, raffinose, and sucrose (Imamura et al., 1994).

The ability of β-fructofuranosidase from *Bifidobacterium animalis* subsp. *lactis* DSM 10140^T to cleave a variety of FOS has been characterized (Janer et al., 2004). Its gene was cloned and the deduced amino acid sequence of 532 residues (59.4 kDa) appeared to be identical to the β-fructofuranosidase from the same strain that was described by Ehrmann et al. (2003). However, there were some discrepancies between the results reported in the two papers, namely differences in the similarity to CscA from *Escherichia coli* (41% vs 16%), activity of the enzyme towards sucrose (6% vs 100%), and a high activity (100%) with the oligofructose Raftilose.

An operon involved in FOS breakdown has been identified in the genome of *Bifidobacterium breve* UCC 2003. This 2.6 kb transcriptional unit was comprised of three genes that encoded a putative permease, a conserved hypothetical protein, and a β-fructofuranosidase (Ryan et al., 2005).

In *Bifidobacterium animalis* subsp. *lactis*, an intracellular endopeptidase (PepO) was identified and characterized. The gene encoding an endopeptidase O was cloned. The product is a 74 kDa monomer member of the M13 peptidase family of zinc metallopeptidases and displays 67.4% sequence similarity with the predicted PepO protein from *Bifidobacterium longum* subsp. *longum* (Janer et al., 2005).

Urease activity. Four hundred and fourteen *Bifidobacterium* strains representing 21 species of the genus were examined for urease activity. The strongest ureolytic strains belonged mainly to *Bifidobacterium longum* subsp. *suis*; more than 80% of the strains of this species were ureolytic. Ureolytic strains were found in all species except for *Bifidobacterium cuniculi*. The enzyme is apparently not inducible; neither organic nitrogen nor urea influenced urease production. Less than 10% of *Bifidobacterium breve* and *Bifidobacterium longum* subsp. *longum* strains are ureolytic, i.e., "human" bifidobacteria species, and *Bifidobacterium bifidum* is only weakly ureolytic (Crociani and Matteuzzi, 1982).

Nitrate reduction. Bifidobacteria are generally not considered to reduce nitrate, although cells grown in the presence of lysed red cells may do so. Cytochrome *b* and cytochrome *d* are synthesized under these growth conditions (Van der Wiel-Korstanje and Vries, 1973).

Genetics. The acquisition of the completed genome sequence of a microbe is an essential step in deciphering the function of each gene within a genome and provides invaluable information on the functional characteristics of the organism and on relationships between the microbes and the host. Currently, one genome of *Bifidobacterium adolescentis* (ATCC 15703^T, GenBank accession no. AP009256), one of *Bifidobacterium animalis* subsp. *lactis* (AD011, GenBank no. CP001213), two genomes of *Bifidobacterium longum* subsp. *longum* (NCC2705, GenBank no. AE014295; DJO10A, GenBank no. CP000605), and one of *Bifidobacterium longum* subsp. *infantis* (ATCC 15697^T, GenBank no. CP001095) have been sequenced completely (Kim et al., 2009; Leahy et al., 2005; Schell et al., 2002; Sela et al., 2008). These genomes show high sequence similarity throughout the chromosome with some regions exclusive to each strain (Ventura et al., 2009). Sequencing of the genomes of the following strains are in progress (GENOME PROJECT; http://www.ncbi.nlm.nih.gov/sites/entrez): *Bifidobacterium adolescentis* strain L2-32; *Bifidobacterium angulatum* DSM 20098^T; *Bifidobacterium animalis* subsp. *lactis* strains BB12, B1-04, DSM 10140^T, HN019, and V9; *Bifidobacterium bifidum* strains BGN4, DSM 20456^T, and NCIMB 41171; *Bifidobacterium breve* DSM 20213^T and UCC 2003; *Bifidobacterium catenulatum* DSM 16992; *Bifidobacterium dentium* ATCC 27678, Bd1, and JCVIHMP023; *Bifidobacterium gallicum* DSM 20093^T; *Bifidobacterium longum* subsp. *longum* strain BORI; *Bifidobacterium longum* subsp. *infantis* ATCC 55813 and CGUG 52486; and *Bifidobacterium pseudocatenulatum* DSM 20438^T.

The 2.26 Mbp genome sequence of an infant-derived strain of *Bifidobacterium longum* subsp. *longum* has been determined and 1730 possible coding sequences organized in a circular chromosome with a G+C content of 60 mol% have been identified. Bioinformatic analysis revealed several physiological traits that could partially explain the successful adaptation of this organism in the colon. An unexpectedly large number of the predicted proteins appeared to be specialized for catabolism of a variety of oligosaccharides, some possibly released by rare or novel glycosyl hydrolases acting on "nondigestible" plant polymers or host-derived glycoproteins and glycoconjugates. This ability to scavenge from a large variety of nutrients probably contributes to the competitiveness and persistence of bifidobacteria in the colon (Schell et al., 2002).

The genome of *Bifidobacterium longum* subsp. *infantis* strain ATCC 15697^T has also been sequenced. It is the largest bifidobacterial genome reported to date with its single circular chromosome consisting of 2,832,748 bp (Sela et al., 2008). This genome reflects a competitive nutrient utilization strategy targeting milk-borne molecules that lack a nutritive value to the neonate. Several chromosomal loci reflect potential adaptation to the infant host including a 43 kbp cluster encoding catabolic genes, extracellular solute-binding proteins, and permeases predicted to be active on milk oligosaccharides. An examination of *in vivo* metabolism has detected the hallmarks of milk oligosaccharide utilization via the central fermentative pathway using metabolomic and proteomic approaches. Finally, conservation of gene clusters in multiple isolates corroborates the genomic mechanism underlying milk utilization for this infant-associated phylotype (Sela et al., 2008). The analyses of oligosaccharides present in human milk and of the metabolic capabilities of infants and of this strain to utilize these compounds provide the basis for the hypothesis of a three-way evolutionary mechanism: human milk–infant–bifidobacteria. Human milk is the source of oligosaccharides, which pass undigested through the infant intestine and are utilized by bifidobacteria, which are beneficial for the infant host.

Analysis of the *Bifidobacterium breve* genome has revealed that the system for exporting proteins in this organism is similar to that of other Gram-stain-positive bacteria. These proteins contain either a signal peptide or a number of transmembrane regions which can be important in the interaction of *Bifidobacterium breve* with the environment of its host (MacConaill et al., 2003). The dnaK operon organization of *Bifidobacterium breve* is almost identical to other presumed dnaK regions of other sequenced *Bifidobacterium* species and to that of other *Actinobacteridae* (Ventura et al., 2005). Other genes important in the shock response of *Bifidobacterium* have been characterized, such as *dnaJ*, *hrcA*, *groEL*, *clpB*, and *clpP* (Ventura et al., 2004).

Different kinds of analytical genetic methods have been used to discriminate between bifidobacteria at the genus, species, and strain levels.

16S rRNA gene sequence analyses are replacing 16S rRNA cataloguing and reverse transcriptase sequencing (Garrity and Holt, 2001; Ludwig and Klenk, 2001). The 16S rRNA gene sequence is considered to be a convenient phylogenetic characteristic and has been used extensively in taxonomic studies of the genus *Bifidobacterium*. Results from these genetic techniques are in fair agreement with 16S rRNA ribotyping data (Sakata et al., 2006).

Pulsed-field gel electrophoresis (PFGE), following genomic digestion with rare-cutting restriction enzymes, has been reported to discriminate effectively between strains of several human and animal *Bifidobacterium* species (O'Riordan and Fitzgerald, 1997; Roy et al., 1996; Simpson et al., 2003). A number of PFGE macro-restriction patterns from porcine cecum strains differed by only a single DNA fragment. It is possible that the extra band seen in these patterns represents an insertion of a fragment with two restriction sites separated by a distance equal to the size of the insertion. However, it was considered more likely that the fragment represented the presence of a putative plasmid.

Fluorescent *in situ* hybridization (FISH) allows direct enumeration of fecal microbiota. It is dependent on the availability of the 16S rRNA gene sequence in databases and effective probe design and validation (Harmsen et al., 2000; Langendijk et al., 1995). FISH has also been adapted for use with flow cytometry; this procedure allows for higher throughput analysis (Rochet et al., 2004; Zoetendal et al., 2002).

PCR of targeted genes, such as 16S rRNA (Matsuki et al., 1999, 1998) or RecA (Kullen et al., 1997), has been used to detect members of the genus and particular species of bifidobacteria.

Quantitative PCR, i.e. real-time PCR, is a sensitive and discriminating method that has been used to quantify bifidobacterial nucleic acids. The real-time PCR TaqMan (Applied Biosystems) assay has been used for bifidobacterial and intestinal microbiota assessment (Gueimonde et al., 2004; Hopkins et al., 2005; Matsuki et al., 2004; Requena et al., 2002).

Another method used to differentiate between *Bifidobacterium* species is amplified rDNA restriction analysis (ARDRA) (Heyndrickx et al., 1996; Krizová et al., 2006; Roy and Sirois, 2000; Ventura et al., 2001). In addition, a PCR technique targeting the transaldolase gene followed by denaturing gradient gel electrophoresis (DGGE) has been designed by Requena et al. (2002). The multiplex PCR technique can simultaneously accomplish the rapid identification and correct differentiation of several bifidobacterial species (Mullié et al., 2003).

PCR-restriction fragment length polymorphism (RFLP) based on 16S rRNA gene sequences has been used to distinguish between human- and animal-borne bifidobacterial strains (Delcenserie et al., 2004). This technique has also been used to differentiate between *Bifidobacterium* species and subspecies (Ventura et al., 2003).

DGGE and variations of this method, such as temperature gradient gel electrophoresis (TGGE), nested-PCR-DGGE, or combinations of DGGE and TGGE, have been used to monitor microbiota community shifts rapidly and to compare microbial communities between different people, different intestinal locations, and diet (Favier et al., 2002; Mangin et al., 2006; Satokari et al., 2001; Temmerman et al., 2003).

Plasmids. When 1461 isolates, representing 24 species of the genus, were examined for the presence of plasmids about 20% of them were found to be positive (Sgorbati and London, 1982). However, only members of four species contained these elements, namely *Bifidobacterium longum* subsp. *longum*, the predominant bifidobacterial species in the human intestine, *Bifidobacterium pseudolongum* subsp. *globosum*, the most common bifidobacterium in animals, and *Bifidobacterium asteroides* and *Bifidobacterium indicum*, which are found exclusively in the intestines of honey bees. *Bifidobacterium longum* subsp. *longum* strains have multiple-plasmid patterns (1.25–9.5 MDa), and *Bifidobacterium pseudolongum* subsp. *globosum* strains each contain one plasmid of three molecular mass classes of (13.5, 24.5, and 46 MDa). Multiple patterns were seen in *Bifidobacterium asteroides* (1.2–22 MDa), whereas 60% of the plasmid-bearing *Bifidobacterium indicum* isolates contained one 22 MDa plasmid. It is noteworthy that *Bifidobacterium longum* subsp. *infantis*, the species most closely related to *Bifidobacterium longum* subsp. *longum*, does not contain plasmids, although strains of both species have been isolated from the same specimens. Phenotypic properties have yet to be correlated with the presence of plasmids (Sgorbati and London, 1982). The 13 plasmid patterns of *Bifidobacterium longum* subsp. *longum* contain only a few homologous structures, whereas the 14 patterns found in *Bifidobacterium asteroides* are structurally more heterogeneous (Sgorbati et al., 1986b). Strains of *Bifidobacterium longum* subsp. *longum* liberate phage particles after UV or mitomycin C treatment, but there is no correlation with their plasmid complement (Sgorbati et al., 1986a, 1983). Plasmids have also been isolated from *Bifidobacterium breve* strains (Bourget et al., 1993; Iwata and Morishita, 1989).

All the plasmids investigated so far are cryptic. Only in *Bifidobacterium pseudolongum* subsp. *globosum* was a relationship found between plasmid and auxotrophy for L-leucine (Mattarelli and Biavati, 1999a). Some plasmids have been characterized at the sequence level (Corneau et al., 2004; Mattarelli et al., 1994; Matteuzzi et al., 1990; Park et al., 1997; Tanaka et al., 2005). Two plasmids were reported to replicate via a rolling circle replication mechanism (O'Riordan and Fitzgerald, 1999; Park et al., 1999) and one has been shown to replicate via theta replication (Lee and O'Sullivan, 2006). A number of cloning vectors have been constructed with plasmids from *Bifidobacterium* and *E. coli* and transformed into both species by electroporation (Lee and O'Sullivan, 2006; Matsumura et al., 1997; Missich et al., 1994; Rossi et al., 1996, 1998). In all cases, transformation efficiency in *Bifidobacterium* was very low and attempts have been made to optimize it (Argnani et al., 1996).

Antibiotic or drug sensitivity. Resistance (with respect to achievable serum levels) to aminoglycosides (framycetin, gentamicin, kanamycin, neomycin, paramycin sulfate, and streptomycin), polypeptides (polymixin B), quinolones (nalidixic acid and ofloxacin), and other antibiotics (fusidic acid and metronidazole), and susceptibility to β-lactams (amoxycillin, ampicillin, cefalothin, cefotaxine, cefoxitin, co-amoxiclav, imipenem, oxacillin, penicillin G, piperacillin, and ticarcillin), coumarin

(novobiocin), ketolide (telithromicin), lincosamide (lindamycin), macrolides (erythromycin, oleandomycin, and spiramycin), streptogramin (pristinamycin), oxazolidinone (linezolid), polypeptide (bacitracin), glycopeptide (teicoplanin), and other antibiotics (chloramphenicol, lincomycin, and rifampin) are a general feature among *Bifidobacterium* species (Charteris et al., 1998; Lim et al., 1993; Matteuzzi et al., 1983). The newly commercialized molecules gatifloxacin, linezolid, and telithromycin were found to be active with MIC_{50} of 1 µg/ml (Moubareck et al., 2005). It can be concluded that the genus *Bifidobacterium* exhibits uniform sensitivity towards the most common antibiotics. However, sensitivity towards antibiotics such as cefhalotin, cefotetan, gentamicin, kanamycin, metronidazole, nalidixic acid, neomycin, ofloxacin, polymyxin B, rifampin, and streptomycin varies greatly within species, ranging from 10–500 µg/ml or more of antibiotic.

Intrinsic resistance to aminoglycosides is probably due to the lack of cytochrome-mediated drug transport among anaerobes (Bryan et al., 1979). Resistance to metronidazole varies among *Bifidobacterium* species. Metronidazole activity is due to the preferential reduction of the parent compound by the bacterial ferridoxin system leading to the generation of an intermediate product responsible for breaks in double-stranded DNA (Bezkorovainy and Miller-Catchpole, 1989). Some strains of bifidobacteria lack the ferridoxin system responsible for the reduction of the parent compound and present a high degree of resistance to metronidazole, a drug active against virtually all obligate anaerobes (Moubareck et al., 2005).

Discordant results have been reported regarding susceptibility to the glycopeptide vancomycin. Some workers (Lim et al., 1993; Matteuzzi et al., 1983; Moubareck et al., 2005) demonstrated vancomycin susceptibility as a general characteristic of bifidobacteria, whereas Charteris et al. (1998) reported resistance to vancomycin. This discrepancy may be due to the use of different assay methodologies, since vancomycin is reported to diffuse poorly in agar media (Thomson et al., 1995). Sensitivity to tetracyclines (tetracycline and minocycline) was shown to be inter- and intra-specifically variable (Matteuzzi et al., 1983). The tetracycline-resistance gene tet(W) has been detected in *Bifidobacterium animalis* subsp. *lactis* DSM 10140^T (Kastner et al., 2006). In *Bifidobacterium longum* subsp. *longum*, the presence of a cholate transporter has been shown and seems to be functionally related to the efflux system encoded by the *ctr* gene, which may contribute to antibiotic and bile resistance (Price et al., 2006). *Bifidobacterium breve* is generally more resistant to antibiotics than other *Bifidobacterium* species (Moubareck et al., 2005). Margolles et al. (2005) were the first to provide evidence for the involvement of a membrane protein from *Bifidobacterium breve* that conferred moderate resistance to macrolides when expressed in the heterologous host *Lactococcus lactis*.

The susceptibility of bifidobacteria to antibiotics is highly relevant to an understanding of alterations in the normal gut flora when antibiotics are used, as well as in selecting bifidobacterial strains as probiotics. Bifidobacteria are natural inhabitants of gastrointestinal microbiota and exert several health-promoting effects. When the intestinal microbiota are exposed to antibiotics, the presence of antibiotic resistance in bifidobacteria might be positive in reducing alterations of the normal gut flora. The relative bifidobacterial resistance to metronidazole might be beneficial in cases of co-administration of bifidobacteria with this antibiotic in preventing antibiotic-associated diarrhea. It should be noted that the therapeutic antibiotic dosage which reaches the colon may be lower than the initial dose because antibiotics are adsorbed mainly in the ileum. Bifidobacteria therefore survive better *in vivo* than *in vitro*.

In other instances, the presence of microbial resistance to antibiotics might be negative. Thus, antibiotic resistance may be transferred to other micro-organisms leading to a rapid increase in antibiotic resistance in human-pathogenic bacteria, particularly with respect to nosocomial infections (Scott et al., 2000). It is important, therefore, that bifidobacterial probiotic strains are free of transferable antibiotic-resistance determinants. However, bifidobacteria, with their low natural and acquired resistance to antibiotics, appear to be safe for use in healthy populations (Moubareck et al., 2005).

Bacteriocins. These antimicrobial peptides have a relatively narrow specificity against closely related Gram-stain-positive organisms (Riley and Wertz, 2002). They have the potential to inhibit the growth of pathogens and to prevent microbial food spoilage. The bactericidal action of bifidobacteria is ascribed to the production of some kind of antimicrobial agent in addition to their pH-reducing effect (Fujiwara et al., 1997; Gibson and Wang, 1994a; Meghrous et al., 1990). Only a limited number of studies have focused on the characterization of antimicrobial peptides synthesized by *Bifidobacterium* species. So far, only some infant *Bifidobacterium* isolates have been shown to produce antimicrobial peptides against *Listeria monocytogenes*. A unique bacteriocin, bifidocin B, from *Bifidobacterium bifidum* NCFB 1454, which is active against Gram-stain-positive bacteria, has been purified (Touré et al., 2003; Yildirim and Johnson, 1998; Yildirim et al., 1999). Bacteriocin-like compounds have been identified in human fecal *Bifidobacterium* strains that show antibacterial activity towards species of the genera *Aeromonas*, *Arcobacter*, *Campylobacter*, *Helicobacter*, and *Vibrio* (Collado et al., 2005).

Pathogenicity. Bifidobacteria have been isolated occasionally from clinical material (Biavati et al., 1982) and, although implicated in some opportunistic infections (Bezkorovainy and Miller-Catchpole, 1989), they are generally regarded as nonpathogens. *Bifidobacterium breve* and *Bifidobacterium longum* have been isolated occasionally from human clinical material (Biavati et al., 1982). Predisposing factors such as ongoing infections (Prévot et al., 1967) or contact with contaminated material (Ha et al., 1999) may lead to bifidobacteria being associated with infections. Some bifidobacterial strains have been reported to participate in soft-tissue infections initiated by mixed bacterial populations. Most strains of *Bifidobacterium dentium* have been isolated from human dental caries and plaque; this organism is the only *Bifidobacterium* species found at this site. *Scardovia inopinata* and *Parascardovia denticolens*, members of the family *Bifidobacteriaceae*, have also been isolated from this location (Crociani et al., 1996; Jian and Dong, 2002; Scardovi and Crociani, 1974). Strains of *Bifidobacterium appendicitis*, a synonym of *Bifidobacterium dentium* (Scardovi and Crociani, 1974), have been found in human clinical material (Prévot et al., 1967). *Actinomyces eriksonii* (Georg et al., 1965), later named *Bifidobacterium eriksonii* by Holdeman and Moore (1970) and recognized genetically as *Bifidobacterium dentium* (Scardovi et al., 1979a), has been isolated

primarily from human abscesses. Thus, *Bifidobacterium dentium* appears to have the most likely pathogenic potential amongst members of the genus *Bifidobacterium* (Beighton, 2005).

Ecology. Bifidobacteria are typically found in the alimentary tracts of human infants and adults. Many factors control the number and the composition of microbial populations in different regions of the gastrointestinal tract. Ways of restoring or maintaining a proper microbial balance in the gastrointestinal tract have been investigated extensively (see Bifidobacteria as health-promoting agents below). Bifidobacteria coexist with a large variety of bacteria, most of which are obligate anaerobes. Components of this microbiota are different in the different areas of the gastrointestinal tract (Moore et al., 1969). The obligate anaerobes in this complex microbiota are in part unknown, although significant advances have been made using appropriate identification techniques, such as the use of molecular probes. Furthermore, it seems likely that particular ecotypes (or biovars) probably have more ecological significance in these habitats than the species to which they belong (Benno and Mitsuoka, 1986; Mitsuoka, 1984; Mitsuoka and Kaneuchi, 1977). Indeed, all factors that pertain to and influence natural genetic variation of single bacterial populations should be studied (Milkman, 1975).

In studies on the ecology of bifidobacteria performed in the Microbiology Section of the Department of Agroenvironmental Technology, Bologna University, Italy, a large number of strains (at present more than 7000) has been isolated from many different sources (Table 21). They are now maintained in the BUSCOB collection (Bologna University Scardovi Collection of Bifidobacteria). Studies on the distribution of bifidobacteria in feces of both infants (Biavati et al., 1984) and adults (Biavati et al., 1986), the human vagina (Crociani et al., 1973), or "pathological conditions" such as dental caries (Crociani et al., 1996) and stomach hypochlorhydria (unpublished data) demonstrate that the adaptation of the species of human origin to the five habitats is different. *Bifidobacterium bifidum* and *Bifidobacterium longum* subsp. *longum*, for example, are the most represented species in the intestinal tract of infants and adults, whereas *Bifidobacterium dentium* together with the *Bifidobacteriaceae* taxa *Scardovia inopinata* and *Parascardovia denticolens* are typical of dental caries and hypochlorhydric stomach. *Bifidobacterium adolescentis*, *Bifidobacterium bifidum*, *Bifidobacterium longum* subsp. *longum*, and *Bifidobacterium breve* are typically found in the vagina.

Furthermore, bifidobacteria have been isolated from many animals and from honey bees. In general, *Bifidobacterium* species are specific either to humans or animals. The same *Bifidobacterium* species found in the intestinal microbiota of suckling calves and breast-fed infants are exceptions. Some species, 15 out of 32, are host-specific and they are typical of a given animal habitat.

Eleven species of *Bifidobacterium* have been found in sewage: six are from humans and five are from animals. *Bifidobacterium minimum* and *Bifidobacterium subtile* were originally isolated from sewage (Biavati et al., 1982). These two species have not been isolated from different habitats for two decades, thus raising the exciting question of the possible development of bifidobacteria in extraenteral ecological niches. Unexpectedly, *Bifidobacterium minimum* was isolated from a rabbit cecum (Simpson et al., 2003) and, in 2009, *Bifidobacterium subtile* was isolated from human caries lesions (Mantzourani et al., 2009). The isolation of *Bifidobacterium minimum* and *Bifidobacterium subtile* confirm that sewage is not a habitat for bifidobacteria.

Bifidobacterium animalis subsp. *lactis* was isolated from yogurt, but this cannot be considered an extra-body habitat as these bifidobacteria are added to fermented milk because of their probiotic properties. Their isolation from human feces (Gavini et al., 2001; Masco et al., 2004; Mättö et al., 2004), therefore, is caused by the consumption of probiotic food containing this species. *Bifidobacterium mongoliense* was isolated recently from fermented mare's milk (Watanabe et al., 2009). *Bifidobacterium thermacidophilum* subsp. *thermacidophilum* and *Bifidobacterium thermacidophilum* subsp. *porcinum* (Dong et al., 2000; Zhu et al., 2003) were described recently. They were isolated from an anaerobic digester used to treat wastewater from a bean-curd farm and from the feces of a piglet, respectively. These species differed from other *Bifidobacterium* species by their ability to grow at 49.5°C and in media with an initial pH of 4.0. *Bifidobacterium scardovii*, isolated from human blood, was described recently by Hoyles et al. (2002). Other recently described species are *Bifidobacterium tsurumiense*, isolated from hamster dental plaque (Okamoto et al., 2008), and *Bifidobacterium bombi*, isolated from the digestive tract of bumblebees (Killer et al., 2009).

Bifidobacteria as health-promoting agents: probiotic, prebiotic, and symbiotic substances. The term probiotic (Parker, 1974) is a relatively new word meaning "for life" and it is used currently to indicate bacteria associated with beneficial effects for humans and animals. A more recent, but probably not the last definition for probiotic is "live micro-organisms, which when consumed in adequate amounts, confer a health effect on the host" (Guarner and Schaafsma, 1998).

Members of the genera *Bifidobacterium* and *Lactobacillus* are considered health-promoting constituents of the gut microbiota and are mainly, but not exclusively, used as probiotic micro-organisms (Leahy et al., 2005). A growing number of probiotic foods are available to the consumer. In the last 20 years, there has been an increased commercial and scientific interest in members of the genus *Bifidobacterium*. Health benefits associated with bifidobacteria include the treatment and prevention of gastrointestinal disorders and the maintenance of digestive health (Snelling, 2005), alleviation of lactose intolerance (Vesa et al., 2000), resistance to microbial infections (Servin, 2004), protection against pathogens (Gill, 2003), enhancement of the immune system (Roller et al., 2004; Tlaskalová-Hogenová et al., 2004), management of allergic disorders (Bienenstock et al., 2002), cancer prevention (Rafter, 2002), and reduction of serum cholesterol (St-Onge et al., 2000; Xiao et al., 2003). Recently, the interesting properties of folate production by bifidobacteria have been investigated (Pompei et al., 2007).

Another approach to increasing the beneficial bifidobacterial population of the gastrointestinal microbiota is to add prebiotic substances to the diet. The word prebiotic is defined as "non-digestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon that can improve the host's health" (Gibson and Roberfroid, 1995). In order to be effective, prebiotic components have to be partially undigested and unabsorbed in the small intestine to provide fermentable substrates for the colon microbiota. They should also stimulate the growth of health-promoting bacteria (mainly bifidobacteria and lactobacilli) and not that of pathogenic bacteria. FOS, lactulose, and GOS are all popular prebiotics (Manning and Gibson, 2004). The concept of prebiotics fundamentally shares

the same objective as probiotics albeit via a different mechanism. The simultaneous administration of prebiotics and probiotics goes under the name "synbiotics" (Tuohy et al., 2005).

An area which promises to be very interesting in the immediate future is that of probiogenomics, which should cast light on how the *Bifidobacterium* genome has evolved from its ancestral prototype to the that present in the species we know today. Bioinformatic analysis of the *Bifidobacterium* genome has revealed a high number of components that can be studied in order to elucidate both the physiology of the microbiota and microbe–host interactions (Ventura et al., 2009). These new approaches to studying probiotics will help in the selection of strains on the basis of physiologically relevant characteristics for the host.

Isolation procedures

A large variety of media have been devised for the isolation and enumeration of bifidobacteria in natural habitats. Ingredients include human milk, liver or meat extracts, sheep or horse blood, tomato juice, and a variety of peptones (Biavati and Mattarelli, 2001). In addition, antibiotics or other ingredients have been used to improve selectivity. Iodoacetic acid, kanamycin, nalidixic acid, polymixin and 2,3,5-triphenyltetrazolium chloride (Muñoa and Pares, 1988), bromocresol green, nalidixic acid and neomycin (Resnick and Levin, 1981), lithium chloride, neomycin, paramomycin and sodium propionate (Mitsuoka et al., 1965), propionic acid (Beerens, 1990), lithium chloride, raffinose and sodium propionate (Hartemink et al., 1996), and lithium chloride and sodium propionate (Lapierre et al., 1992) have all been used as selective agents.

Known bifidobacteria are resistant to certain antibiotics (see above), but the intraspecific variations are large. At present, preference should be given to substrates that permit satisfactory growth of the largest number of known bifidobacteria added with mupirocin. The ingredients of choice are trypticase and phytone and the formula which, in our hands, has proved to be satisfactory for isolating bifidobacteria from all known habitats is TPY medium (trypticase, 10 g; phytone, 5 g; glucose, 5 g; yeast extract, 2.5 g; Tween 80, 1 ml; cysteine hydrochloride, 0.5 g; K_2HPO_4, 2 g; $MgCl_2 \cdot 6H_2O$, 0.5 g; agar, 15 g; and distilled water to 1000 ml) plus 1 ml/l of a freshly prepared ethanol stock solution of 100 mg/ml of mupirocin which is added to the already sterilized medium. Dilutions can be made with physiological solutions. Petri dishes with vents are incubated at 37–39°C in anaerobic jars with a gas generator system (Merck system). Colonies are transferred to stabs of the same medium with 0.5% agar. After growth has reoccurred, stabs are kept at 3–4°C in anaerobic jars. Transfers should be made every 2 weeks.

Maintenance procedures

Cultures may be maintained for short periods on TPY slants or as TPY liquid cultures under anaerobic conditions and should be subcultured every 2–4 weeks. This procedure is not satisfactory for long-term storage as some properties are liable to change on repeated subculture. However, strains may be maintained for 1–2 years at low temperatures (−135°C) after centrifugation and addition of a cryoprotective agent containing 10% skim milk and 0.3% yeast extract in distilled water (0.3 g wet pellet of cells/ml cryoprotective agent). Freeze-drying is the best maintenance procedure for long-term storage (40 years).

Enzymes used for species and group differentiation

Starch gel electrophoresis revealed three types of F6PPK in bifidobacteria (Table 21) (Scardovi et al., 1971a). The most anodal type was detected in species found in the intestine of honey bees; the type found in species from humans (human type) migrated less, but the least anodal type characterized species found in animals (animal type). F6PPK from *Bifidobacterium pseudolongum* subsp. *globosum* (animal type) and *Bifidobacterium dentium* (human type) have been purified (Sgorbati et al., 1976). The animal type has properties similar to those found in *Acetobacter xylinum* (Schramm et al., 1958) and is also active towards xylulose 5-phosphate. The human type has different properties (activators, pH range of activity, heat inactivation) and only cleaves fructose 6-phosphate (Sgorbati et al., 1976). The molecular mass of F6PPK can be used to differentiate between animal and human strains (Grill et al., 1995; Sgorbati et al., 1976).

The ecological groups of *Bifidobacterium* species have also been distinguished on an immunological basis (Sgorbati and London, 1982). Isozyme patterns can also be used to identify species. Isozymes of transaldolase and 6-phosphogluconate dehydrogenase (6PGD) were studied by starch gel electrophoresis in 1206 strains belonging to 24 *Bifidobacterium* species (Scardovi et al., 1979a). Fourteen isozymes of transaldolase and 19 of 6PGD were identified and numbered and patterns or zymograms were thus obtained for each species (Table 21); 60% of the strains were identified on this basis. An additional 20% of the strains were assigned to species based on the electrophoretic behavior of their 3-phosphoglyceraldehyde dehydrogenase (Scardovi et al., 1979a).

Antisera against eight purified transaldolases further established natural relationships among *Bifidobacterium* species (Sgorbati, 1979; Sgorbati and London, 1982; Sgorbati and Scardovi, 1979). Transaldolases selected on the basis of their electrophoretic behavior (see above) were examined from *Bifidobacterium angulatum*, *Bifidobacterium asteroides*, *Bifidobacterium cuniculi*, *Bifidobacterium globosum* subsp. *globosum*, *Bifidobacterium infantis*, *Bifidobacterium minimum*, *Bifidobacterium longum* subsp. *suis*, and *Bifidobacterium thermophilum*. Indices of dissimilarity and immunological distances were determined using microcomplement fixation data. The various purified transaldolases cannot be distinguished on the basis of the usual parameters, such as molecular mass, substrate affinity, pH range, and type of acceptors (V. Scardovi, unpublished data).

The segregation of *Bifidobacterium* species into four distinct clusters that correlated with the groups made on the basis of their ecological distribution suggests that a "subdivision of the genus into four subgenera would more accurately reflect the group's natural history" (Sgorbati and London, 1982).

The starch-gel horizontal electrophoresis system of Smithies (1955) is recommended for the detection of enzymes.

Transaldolases. Tris (16.3 g) and citric acid monohydrate (9.0 g/l) (pH 7.0) is used as the bridge buffer. It is diluted 1:15 for use as a gel buffer. Hydrolyzed starch, 90 g/l, is added, the mixture is boiled for 5 min (keep agitated) and gas removed under reduced pressure. The liquid is poured into a plastic three-frame mold (12.0 × 37.0 × 0.9 cm accommodates 12 samples at a time). Samples of bacterial extracts [cells suspended in 0.05 M phosphate buffer (pH 7.0), sonicated, and centrifuged],

5–10 µl in 0.5 × 0.5 cm Whatman 3-mm paper cuts, are generally run for 15–20 h with a current of 15–20 mA.

The middle slab is used preferably for staining by the flooding technique. The developing solution contains (per 100 ml of distilled water): fructose 6-phosphate (sodium salt, 98% purity; Sigma), 400 mg; sodium arsenate, 370 mg; glycine, 240 mg; NAD, 13 mg; D-erythrose 4-phosphate (60–75% purity; Sigma), 16 mg; phenazine methosulfate, 2 mg; Nitro Blue Tetrazolium (NBT; Sigma), 20 mg; and about 130–150 IU glyceraldehyde-3-phosphate dehydrogenase.

6-Phosphogluconate dehydrogenases (6PGD). Use trisodium citrate·$2H_2O$ (120 g/l) (pH 7.0 with citric acid) as the bridge buffer, and histidine (0.75 g) plus NaC1 (1.5 g/l) (pH 7.0) as gel buffer. Prepare the gel as for detecting transaldolases. The developing solution is made as follows: 0.5 M Tris/HCl buffer, pH 7.0, 10 ml; 6-phosphogluconate (trisodium salt; Sigma) 250 mg; NADP, 20 mg; NBT, 20 mg; phenazine methosulfate, 2 mg; and distilled water, 90 ml.

The electrophoretic patterns of cellular proteins on PAGE (Moore et al., 1980) were used to confirm the taxonomic identification of 1094 bifidobacteria strains representing all known species of the genus. Excellent correlation was found between electrophoretic and DNA–DNA hybridization data. On this basis, one species was revived (*Bifidobacterium coryneforme*) and two others were proposed from previously recognized DNA homology groups (*Bifidobacterium minimum* and *Bifidobacterium subtile*) (Biavati et al., 1982).

In addition, a sort of "genus band" is clearly visible in all bifidobacteria gel electrophoretic patterns. This band migrates to the same position for all strains with the exception of *Bifidobacterium boum* where it is somewhat less anodic. The presence of this "genus band" is a good indication that an unknown organism belongs to the genus *Bifidobacterium* (Biavati et al., 1982). In *Bifidobacterium animalis*, it is possible to discriminate between the subspecies *animalis* and *lactis* based on PAGE patterns. Strains of *Bifidobacterium animalis* subsp. *animalis* isolated from rats appear to differ from strains of *Bifidobacterium animalis* subsp. *lactis* isolated from chickens, rabbits, and sewage (Biavati et al., 1982). The intestinal origin of *Bifidobacterium animalis* subsp. *lactis* strains isolated from sewage and fermented milk products has been determined by comparing electrophoretograms of cellular soluble proteins (Mattarelli et al., 1992). This procedure was also found to be useful for the rapid identification of unknown bifidobacterial isolates. Computer-assisted numerical comparisons of protein patterns are feasible and a database can be created for identification purposes provided that highly standardized conditions are used for cultivation and electrophoresis; this allows large numbers of strains to be compared and grouped into closely related clusters (Pot et al., 1994).

Procedures for testing special identification characteristics

Identification of a bacterial strain as a member of the genus *Bifidobacterium* is unreliable unless special procedures are used. Morphological properties can be misleading due to unusual and unique traits shown by some species such as *Bifidobacterium angulatum*, *Bifidobacterium asteroides*, and *Bifidobacterium pullorum*. Culture conditions and physiological characteristics are largely shared by other bacteria such as strains of *Actinomyces*, *Corynebacterium*, and *Lactobacillus*. Identification of fermentation products by GC (Holdeman et al., 1977) may be difficult, especially for inexperienced workers, as side reactions forming substantial and variable amounts of formic and succinic acids and ethanol may occur.

The most direct and reliable property for assigning an organism to the genus *Bifidobacterium* is the demonstration of F6PPK activity in cellular extracts. F6PPK is the characteristic key enzyme of "the bifid shunt". This enzyme activity, tested with fructose 6-phosphate as substrate, is apparently absent in anaerobic Gram-stain-positive bacteria with a "pseudobifid" morphology, i.e., *Actinomyces*, *Arthrobacter*, *Corynebacterium*, and *Propionibacterium* (Scardovi and Trovatelli, 1965). Proof of the validity of this test has been furnished by (a) the isolation of anaerobic bacteria from the bovine rumen and from sewage with the morphology and gross physiology of bifidobacteria, but which do not possess F6PPK (V. Scardovi, unpublished data) and (b) recognition of bifidobacteria on this basis, i.e., of bacteria with nonbifid morphology such as *Bifidobacterium pullorum* (Trovatelli et al., 1974) and of bifidobacteria from honey bees (Scardovi and Trovatelli, 1969).

F6PPK test. Reagents are as follows: 1, 0.05 M phosphate buffer, pH 6.5, plus 500 mg/l cysteine; 2, a solution containing 6 mg/ml NaF and 10 mg/ml iodoacetate (potassium or sodium salt); 3, hydroxylamine·HC1, 13.9 g/100 ml water, freshly neutralized with NaOH to pH 6.5; 4, trichloroacetic acid (TCA), 15% (w/v) in water; 5, 4 M HC1; 6, 5% (w/v) $FeC1_3 \cdot 6H_2O$ in 0.1 M HCl; and 7, fructose 6-phosphate (sodium salt; 70% purity), 80 mg/ml in water.

The formation of acetyl phosphate from fructose 6-phosphate is shown by the reddish violet color (absorption maximum at 505 nm) formed by the ferric chelate of its hydroxamate (Lipmann and Tuttle, 1945).

Classical procedure. Cells harvested from 20 ml TPY broth are washed twice with reagent 1 and resuspended in 1.0 ml of the same reagent. Cells are disrupted by sonication in the cold, and 0.25 ml each of reagents 2 and 7 are added to the sonicate. After 30 min incubation at 37°C, the reaction is stopped with 1.5 ml of reagent 3. After 10 min at room temperature, 1.0 ml each of reagents 4 and 5 are added. The mixture may be left at room temperature before the final addition of 1.0 ml of the color-developing reagent 6. Invert tube for mixing. Any reddish violet color that develops immediately is taken as a positive result. A tube without fructose 6-phosphate can serve as a blank to aid the visual comparison. The color becomes more evident after standing, as this allows particles to settle. Warning: avoid heating during sonication because of heat sensitivity of the enzyme.

Modified procedure. A modified procedure of the phosphoketolase test involves an alternative chemical method for cell disruption (Orban and Patterson, 2000). Cells harvested and resuspended in 1 ml reagent 1, as above, are incubated with 0.4 ml cetrimonium bromide (hexadecyltrimethylammonium bromide or CTAB) (450 µg/ml stock solution) for 5 min at room temperature; the same steps as above are then followed. This method is less time-consuming and is an effective alternative to sonication and French press disruption.

Differentiation of the species of the genus *Bifidobacterium*

Differential characteristics for distinguishing between *Bifidobacterium* species are indicated in Table 21. Other diagnostic characteristics are cited in Table 22.

[a] Symbols: +, 90% or more strains positive; –, 90% or more strains negative; v, 11–89% of strains positive; nd, not determined. All strains tested ferment glucose, but not alginate, bovine submaxillary mucin, chondroitin sulfate, dextran, α-D-fucose, D-galacturonate, glycerol, gum karaya, heparin, hyaluronate, lactate, laminarin, ovomucoid, polygalacturonate, or L-rhamnose. *Bifidobacterium psychraerophilum* and *Bifidobacterium thermacidophilum* subsp. *porcinum* have not been tested. All data relating to the degradation of complex carbohydrates are from Crociani et al. (1994). Data for *Bifidobacterium animalis* subsp. *lactis* from Meile et al. (1997); data for *Bifidobacterium gallinarum* from Watabe et al. (1983); data for *Bifidobacterium gallicum* from Lauer (1990); data for *Bifidobacterium thermacidophilum* subsp. *thermacidophilum* from Dong et al. (2000).

[b] A few strains do not ferment this sugar.

[c] A few strains do not ferment this sugar, but for strains that do, fermentation is slow.

[d] Some strains ferment this sugar.

[e] Sugars listed as "v" mainly give erratic results.

[f] A few strains do not ferment pentoses.

[g] Some strains are weak fermenters.

[h] Generally delayed or slight fermentation.

[i] Reported as "sometimes not fermented" (Matteuzzi et al., 1971).

[j] Some strains from sewage ferment this sugar.

[k] Some strains, especially those from rabbit and rat feces, do not ferment this sugar.

[l] Some strains can ferment this sugar weakly.

List of species of the genus *Bifidobacterium*

1. **Bifidobacterium bifidum** (Tissier 1900) Orla-Jensen 1924, 472[AL] (*Bacillus bifidus* Tissier 1900, 86)

bi′fi.dum. L. neut. adj. *bifidum* cleft, divided.

Cells are highly variable in appearance, but some traits observed with cells grown in TPY agar stabs are distinct (Figure 67, panel 1). Groupings of "amphora-like" cells are characteristic (Sundman et al., 1959).

Two biovars are recognized; biovar a predominates in the feces of human adults and biovar b in that of neonates (variants a and b; Reuter, 1963); these variants differ in their fermentation of maltose, melibiose, and sucrose.

Source: the type strain was isolated from the feces of a human infant.

DNA G+C content (mol%): 61 (T_m).

Type strain: Ti (Tissier), ATCC 29521, DSM 20456, JCM 1255, LMG 11041.

Sequence accession no. (16S rRNA gene): M38018.

2. **Bifidobacterium adolescentis** Reuter 1963, 502[AL]

a.do.les.cen′tis. L. n. *adolescens* adolescent; L. gen. n. *adolescentis* of an adolescent.

The cellular morphology is common to that of many other *Bifidobacterium* species (Figure 67, panel 2).

Reuter (1963) named the pentose-fermenting bifidobacteria he first found to predominate in the feces of human adults as *Bifidobacterium adolescentis* and *Bifidobacterium longum* subsp. *longum*. Four biovars were identified, a, b, e, and d, that varied in their ability to ferment mannitol and sorbitol and were serologically distinct (Reuter, 1963).

Among those species which are regularly found in man, *Bifidobacterium adolescentis* occurs most frequently in sewage (Scardovi et al., 1979a). Reuter's biovars b and d, namely those which do not ferment sorbitol, cannot be distinguished phenotypically from *Bifidobacterium dentium* (Table 22) (Scardovi et al., 1979a). Alternatively, the PAGE procedure can be used for differentiation (Biavati et al., 1982).

Source: the type strain was isolated from the feces of a human adult.

DNA G+C content (mol%): 59 (T_m).

Type strain: E194a, ATCC 15703, DSM 20083, JCM 1275, LMG 10502, NCIMB 702204.

Sequence accession no. (16S rRNA gene): M58729.

Additional comments: the genome of *Bifidobacterium adolescentis* ATCC 15703[T] (GenBank accession no. AP009256) has been completely sequenced; its single circular chromosome consists of 2,089,645 bp (GENOME PROJECT, http://www.ncbi.nlm.nih.gov/sites/entrez).

3. **Bifidobacterium angulatum** Scardovi and Crociani 1974, 19[AL]

an.gu.la′tum. L. neut. adj. *angulatum* with angles, angular.

Cells grown in TPY agar stabs generally and characteristically form V (angular) or palisade arrangements similar to corynebacteria; cells are rarely enlarged at the extremities. Branching is absent. This morphological type is unique among bifidobacteria (Figure 67, panel 3).

Anaerobic, but more sensitive to O_2 than most bifidobacteria (measured by the depth of growth in stabs). CO_2 does not affect this sensitivity, but it strongly enhances anaerobic growth.

Some *Bifidobacterium angulatum* strains (20%) ferment sorbitol and thus can be readily distinguished from other *Bifidobacterium* species that ferment this sugar (Table 22). Strains that do not ferment sorbitol can be confused, in the case of doubtful morphology, with *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium pseudolongum* subsp. *pseudolongum*, and with sorbitol-negative strains of *Bifidobacterium pseudocatenulatum* from calf feces [nearly half of the *Bifidobacterium pseudocatenulatum* strains from this source are inactive toward sorbitol (Scardovi et al., 1979b)].

Bifidobacterium angulatum possesses the least anodal transaldolase (number 5) with respect to named *Bifidobacterium* taxa.

Source: first isolated from adult human feces and later found in sewage; the type strain was isolated from the feces of a human adult.

DNA G+C content (mol%): 59 (T_m).

Type strain: B677, ATCC 27535, DSM 20098, JCM 7096, LMG 11039, NCIMB 702236.

Sequence accession no. (16S rRNA gene): M84775.

4. **Bifidobacterium animalis** (Mitsuoka 1969) Scardovi and Trovatelli 1974, 26[AL] (*Bifidobacterium longum* subsp. *animalis* biotype a Mitsuoka 1969, 60)

a.ni.ma′lis. L. neut. gen. n. *animalis* of a living being, an animal.

Cells grown on TPY characteristically show that the central parts are slightly enlarged (Figure 67, panels 4a and 4b). Branching can occur to form cross-like aggregates of four cells that are distally inflated.

Bifidobacteria isolated from feces of calves, sheep, rats, and guinea pigs are very similar phenotypically to *Bifidobacterium longum*, but inactive toward melezitose, and were referred to as a subspecies of *Bifidobacterium longum* (*Bifidobacterium longum* subsp. *animalis* Mitsuoka (1969). Two distinct biovars, a and b, were identified: biovar a was mannose-negative and biovar b was mannose-positive (Mitsuoka, 1969). Mitsuoka's strains R101-8[T] biovar a (ATCC 25527[T]) and C10-45 biovar b were not related to *Bifidobacterium longum* based on DNA homology studies, but one of them (C10-45 biovar b) was related to *Bifidobacterium pseudolongum* (Scardovi et al., 1971b). Strain R101-8[T] was subsequently allotted to a DNA homology group of bifidobacteria isolated from chickens, rats, rabbits, and sewage and proposed as the distinct species, *Bifidobacterium animalis* comb. nov. (Scardovi and Trovatelli, 1974).

CO_2 has no effect upon O_2 sensitivity or anaerobic growth. Cells survive exposure to pH 3–5 for 3 h (Matsumoto et al., 2004). Glucose is fermented using the characteristic enzyme F6PPK in the so-called bifid shunt. Dextrin, D-glucose, maltose, maltotriose, raffinose, and sucrose are fermented, but not starch. Growth occurs in the presence of 4.2% NaCl at 37°C and in 3.0% NaCl at 45°C (Yaeshima et al., 1991).

Isozymes of transaldolase (isozyme 5) and 6PGD (isozymes 8 or 9) possessed by this species show a pattern shared with only a strains of *Bifidobacterium catenulatum* (Table 21).

Fructose-bisphosphate aldolase and G6PDH activities are observed (Scardovi and Trovatelli, 1974).

Biavati et al. (1992a) observed the phenomenon called "phase variation" (Trüper and Krämer, 1981) in members of the two subspecies of *Bifidobacterium animalis*. The transition of colony phenotype accompanied by a dramatic change in cell morphology and dimensions was described. Cells forming transparent (T) colonies, which were minute and mostly spherical, were seen to develop into cells that formed opaque (O) colonies, which had species-specific shapes and dimensions (Figure 69.)

Source: found in calves, chickens, rabbits, feces of rats, sewage, and fermented milk.

DNA G+C content (mol%): 60.1 ± 0.3 (T_m; Scardovi and Trovatelli, 1974).

Type strain: Mitsuoka R101-8, ATCC 25527, DSM 20104, NCIMB 702242, JCM 1190, LMG 10508.

Sequence accession no. (16S rRNA gene): D86185.

Additional comments: Bifidobacterium animalis can be readily differentiated from other *Bifidobacterium* species found in animal habitats that ferment arabinose and xylose (namely, *Bifidobacterium cuniculi*, *Bifidobacterium magnum*, *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium pseudolongum* subsp. *pseudolongum*, *Bifidobacterium pullorum*, and *Bifidobacterium longum* subsp. *suis*) by lactose and salicin fermentation. If a strain ferments both sugars, it can be retained as *Bifidobacterium animalis* [of the species cited above, *Bifidobacterium pullorum* ferments salicin, but not lactose (Table 22)]. "Human" species that ferment pentoses but not starch, such as *Bifidobacterium adolescentis* and *Bifidobacterium dentium*, can be distinguished from *Bifidobacterium animalis* by the absence of gluconate fermentation in *Bifidobacterium animalis* (Table 22).

Bifidobacterium animalis strains were subdivided into the subspecies *animalis* and *lactis* by Masco et al. (2004). This taxonomic rearrangement has been supported by genotypic and phenotypic data. *Bifidobacterium animalis* subsp. *animalis* contains strains isolated from rat feces, whereas *Bifidobacterium animalis* subsp. *lactis* includes strains isolated from chicken and rabbit feces, and from fermented milk and sewage. The two subspecies can also be distinguished by BOX-PCR, fluorescent amplified fragment length polymorphism (FAFLP) DNA fingerprinting, by *atpD* and *groEL* gene sequence typing, and by PAGE electrophoresis (Masco et al., 2004; Mattarelli et al., 1992), and also by their ability to grow in a milk-based medium (Masco et al., 2004). The PAGE protein pattern is distinct from that of all other *Bifidobacterium* species (Biavati et al., 1982). PAGE analysis provides a reliable way of separating *Bifidobacterium animalis* subsp. *lactis* strains isolated from different sources (Mattarelli et al., 1992).

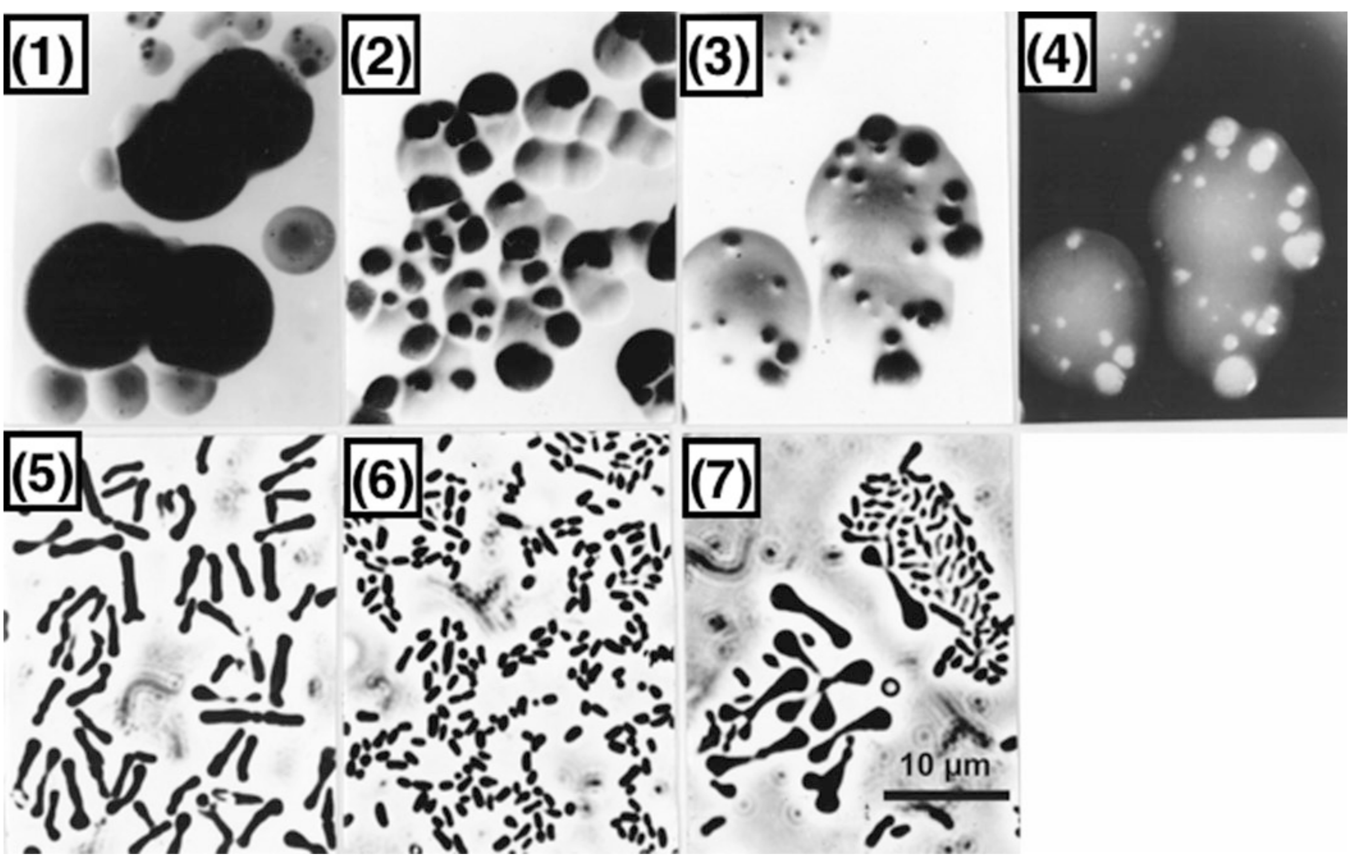

FIGURE 69. *Bifidobacterium animalis* subsp. *lactis* strain P 23 (=ATCC 27536): (1) and (2), transparent (T) and opaque (O) colonies, respectively; (3) and (4), T colonies with O papillae viewed under different illumination; (5) and (6), cells from O and T colonies, respectively; (7), mixed type from TPY stab. Phase-contrast photomicrographs (magnification 1500×).

4a. **Bifidobacterium animalis subsp. animalis** (Scardovi and Trovatelli 1974) Masco, Ventura, Zink, Huys and Swings 2004, 1142[VP] (*Bifidobacterium animalis* Scardovi and Trovatelli 1974, 26; *Bifidobacterium longum* subsp. *animalis* biotype a Mitsuoka 1969, 60)

a.ni.ma′lis. L. neut. gen. n. *animalis* of a living being, an animal.

Strains display characteristics that are typical of *Bifidobacterium animalis* as described above. No growth occurs in slants incubated in air or in air enriched with carbon dioxide. The optimum growth temperature is 39–41°C. Growth does not occur in milk or milk-based media.

Source: strains, including the type strain have been isolated from rat feces.

DNA G+C content (mol%): 61.3 ± 0.0 (T_m).

Type strain: Mitsuoka R101-8, ATCC 25527, DSM 20104, NCIMB 702242, JCM 1190, LMG 10508.

Sequence accession no. (16S rRNA gene): X70971.

4b. **Bifidobacterium animalis subsp. lactis** (Meile, Ludwig, Rueger, Gut, Kaufmann, Dasen, Wenger and Teuber 1997) Masco, Ventura, Zink, Huys and Swings 2004, 1142[VP] (*Bifidobacterium lactis* Meile, Ludwig, Rueger, Gut, Kaufmann, Dasen, Wenger and Teuber 1997, 63)

lac′tis. L. neut. gen. n. *lactis* of milk.

Strains display characteristics that are typical of *Bifidobacterium animalis*. Growth is not seen on agar plates exposed to air, but is evident in cultures containing 10% oxygen in the headspace atmosphere above liquid media. The molar ratio of acetate to lactate from glucose metabolism is about 10:1 under anaerobic conditions, e.g. lactate production is replaced by formate production. The optimum growth temperature is 39–42°C. Growth occurs in milk or milk-based media.

Source: strains have been isolated from chicken and rabbit feces, fermented milk samples, sewage, and recently from human feces (infants and adults) (Gavini et al., 2001; Masco et al., 2004; Mättö et al., 2004). *Bifidobacterium animalis* subsp. *lactis* is a probiotic supplement in the human diet (Biavati et al., 1995; Bouhnik et al., 1992) and, hence, it is reasonable to consider finding it in human feces due to the ingestion of milk products. However, the natural habitat of the taxon is the intestine of chickens and rabbits. The type strain was isolated from fermented milk.

DNA G+C content (mol%): 61.0 ± 0.5 (T_m).

Type strain: UR1, DSM 10140, JCM 10602, LMG 18314.

Sequence accession no. (16S rRNA gene): X89513.

Additional comments: the genome of *Bifidobacterium animalis* subsp. *lactis* AD011 (GenBank accession no. CP001213) has been completely sequenced (Kim et al., 2009); it is smaller than other completely sequenced bifidobacterial genomes reported to date with its single circular chromosome consisting of 1,933,695 bp.

5. **Bifidobacterium asteroides** Scardovi and Trovatelli 1969, 83[AL]

as.te.roi′des. N.L. neut. adj. *asteroides* (from Gr. adj. *asteroeides -es*) star-like.

Cells grown in TPY agar stabs are 2–2.5 µm long, generally occur in pairs with pointed ends, and are slightly curved. They usually show a radial disposition around a common mass of hold-fast material (Figure 67, panel 5). Nutritional or CO_2 deficiencies or growth with certain sugars may induce clavate or spatulate cells with occasional swellings, and irregular or cross-like branching in the central part of the cell body. Colonies are circular, smooth, and convex, with entire edges. The consistency is such that colonies removed by needle can hardly be dispersed in water. Growth in static fluid culture generally causes bacteria to adhere to the glass walls and leaves the liquid clear. CO_2 is required for growth in all media, including stabs. Aerobic growth occurs on slopes only if air is enriched with 10% CO_2. H_2O_2 is decomposed vigorously by cells grown in 90% air + 10% CO_2. In stabs, incubated in CO_2/air, only the lower portions of the growth are catalase-negative. Temperature optimum is 35–36°C; growth does not occur at 21°C or at 42°C after incubation for 7 d. Biotin, nicotinic acid, pantothenate, pyridoxine, riboflavin, and thiamin are required for continued growth in a Bacto vitamin-free Casamino acids-containing substrate.

Fructose-bisphosphate aldolase is not detected in cell-free extracts or in iodoacetate-poisoned cell suspensions. Cell-free extracts possess $NADP^+$-dependent hexose monophosphate dehydrogenases. When 85 strains from very different geographical origins were examined electrophoretically for their transaldolase and 6PGD isozyme content at least eight transaldolases and nine 6PDG were detected; each strain exhibited only one band for each allozyme. *Bifidobacterium asteroides* possesses the least mobile variant of 6PGD (isozyme 13 moves 53, whereas isozyme 1, the most anodal variant, found in *Bifidobacterium pseudocatenulatum*, moves 100) (Scardovi et al., 1979a).

A large variety of extrachromosomal elements of diverse molecular masses ranging from 1.2 to 22 MDa were found in 74 out of 224 members of this species (Sgorbati et al., 1982). The functions encoded by these plasmids are still not known.

Source: normally found in the intestine of western honey bees and occasionally in the hind-gut of *Apis cerana*, an asiatic honey bee. The type strain was isolated from the intestine of *Apis mellifera* subsp. *ligustica*.

DNA G+C content (mol%): 59 (T_m).

Type strain: C 51, ATCC 25910, DSM 20089, JCM 8230, LMG 10735.

Sequence accession no. (16S rRNA gene): M58730.

Additional comments: DNA–DNA homolgy with *Bifidobacterium indicum*, another bifid found in honey bees, is about 30%. Unexpectedly, 50% DNA–DNA homology was shown with *Bifidobacterium choerinum*, a bifid from piglets; otherwise, the DNA is unrelated to that of any other *Bifidobacterium* species.

6. **Bifidobacterium bombi** Killer, Kopečný, Mrázek, Rada, Benada, Koppová, Havlík and Straka 2009, 2023[VP]

bom′bi. L. n. *bombus* a boom, a deep hollow noise, buzzing, also the zoological genus name of the bumblebee; N.L. gen. n. *bombi* of *Bombus*, of a bumblebee

Short and irregularly shaped rods (0.4–0.5 μm wide and 0.9–1.1 μm long) with occasional bifurcations (Figure 67, panel 6). Along the cells are irregular constrictions. Colonies on TPY agar under anaerobic conditions are white, circular, and low convex with sharp undulate edges. Their size can reach 1.0–1.7 mm after 3 d incubation. In culture, the appearance of the cells resembles dividing bacilliform cells frequently forming filaments with irregular contractions and bifurcations. Strictly anaerobic. Optimal temperature for growth is 30°C; maximal temperature is 37°C. Good growth occurs from 10 to 37°C. Very limited growth is observed at 47°C. Minimal initial pH for growth is 4.5.

All strains utilize arbutin, esculin, α-galactoside, gentiobiose, D-glucose, D-mannose, melibiose, D-ribose, salicin, L-arabinose, cellobiose, dulcitol, erythritol, D-galactose, glycerol, glycogen, inositol, inulin, D-lactose, maltose, D-mannitol, L-rhamnose, D-sorbitol, sorbose, and turanose; D- and L-xylose are not utilized.

Isolates produce arginine arylamidase, histidine arylamidase, leucine arylamidase, phenyl arylamidase, proline arylamidase, serine arylamidase, tyrosine arylamidase, β-galactosidase, and α- and β-glucosidases. Catalase-, oxidase-, and urease-negative.

Fatty acids in the cultures contain a low proportion of branched-chain components. In 145 isolates, the dominant fatty acids are oleic ($C_{18:1}$; 7.49%) and arachidic ($C_{20:0}$; 7.18%) acids. *Bifidobacterium bombi* contains a high level of linoleic acid ($C_{18:2}$; 7.34%). Heneicosanoic acid is not present. Four other fatty acids are present: palmitic ($C_{16:0}$; 7.14%), stearic ($C_{18:0}$; 5.91%), behenic ($C_{22:0}$; 5.87%), and tricosanoic ($C_{23:0}$; 5.38%) acids. The content of odd chain fatty acids is high (41.2%, w/v). Increased unsaturated fatty acid content corresponds with lower growth temperature.

Source: isolated from the digestive tract of different bumblebees (*Bombus lucorum*, *Bombus pascuorum*, and *Bombus lapidarius*) in Central Bohemia. The type strain was isolated from the digestive tract content of *Bifidobacterium lucorum* from Central Bohemia, Czech Republic.

DNA G+C content (mol%): 47.3 (T_m), the lowest value found so far in the bifidobacteria.

Type strain: BluCI/TP, ATCC BAA-1567, DSM 19703.

Sequence accession no. (16S rRNA gene): EU127549.

Additional comments: the type strain, BluCI/TP^T, and related isolates were located in the actinobacterial cluster and were closely related to members of the genera *Bifidobacterium*, *Aeriscardovia*, *Parascardovia*, and *Scardovia*. The closest relative of BluCI/TP^T was *Bifidobacterium asteroides* (93% 16S rRNA gene sequence similarity). Because of the low G+C content, the phylogenetic location of this species was verified by phylogenetic analysis using the *hsp60* gene; highest *hsp60* gene sequence similarity of BluCI/TP^T was to *Bifidobacterium asteroides* (82%).

7. **Bifidobacterium boum** Scardovi, Trovatelli, Biavati and Zani 1979b, 308[AL]

bo′um. L. n. *bos* a cow; L. pl. gen. n. *boum* of cattle.

Cells grown on TPY agar are, in general, more irregular than those of *Bifidobacterium thermophilum* and vary greatly between strains (Figure 67, panel 7). Most branched forms are seen in cells grown in air + CO_2. Grows in 90% air + 10% CO_2 without becoming catalase or catalase-like (hemin)-positive. Requirements for growth factors are unknown.

Fructose-bisphosphate aldolase and G6PDH are present in cell-free extracts, as with *Bifidobacterium thermophilum*. The transaldolase isozyme of *Bifidobacterium boum* (number 6) is clearly electrophoretically distinct from that of the majority (93%) of *Bifidobacterium thermophilum* strains (number 8).

The interpeptide bridge of the cell-wall peptidoglycan is Lys–D-Ser–D-Glu and differs from that of the closely related species *Bifidobacterium thermophilum*, which is Orn(Lys)–D-Glu.

The PAGE protein pattern of *Bifidobacterium boum* is distinct and easily distinguishable from that of *Bifidobacterium thermophilum*. The so called "genus band" is slightly less anodal in *Bifidobacterium boum* than in any other *Bifidobacterium* species (Biavati et al., 1982).

Source: the type strain was isolated from bovine rumen.

DNA G+C content (mol%): 60.0 ± 0.2 (T_m).

Type strain: RU917, ATCC 27917, DSM 20432, JCM 1211, LMG 10736.

Sequence accession no. (16S rRNA gene): D86190.

Additional comments: the practical distinction of *Bifidobacterium boum* from *Bifidobacterium choerinum* and *Bifidobacterium thermophilum*, which are often found in the same ecological niches, can be achieved with transaldolase analysis or protein PAGE (see Additional comments under *Bifidobacterium choerinum*).

A few strains isolated from the bovine rumen as biovars of *Bifidobacterium thermophilum* (*Bifidobacterium ruminale*) (Scardovi et al., 1969) were later found to show nearly 70% DNA–DNA relatedness to *Bifidobacterium thermophilum* (Scardovi et al., 1971b). Subsequently, other strains isolated from the bovine rumen were assigned to DNA homology group IV, as they showed 55–75% relatedness to *Bifidobacterium thermophilum* (Trovatelli and Matteuzzi, 1976). Out of a large number of animal strains analyzed by DNA–DNA hybridization, 36 strains from the rumen and five from piglet feces were assigned to the novel species *Bifidobacterium boum* (Scardovi et al., 1979b).

Although *Bifidobacterium boum* does not ferment cellobiose, melezitose, D-mannose, or trehalose, and thus has a more stable sugar fermentation pattern than *Bifidobacterium thermophilum*, the fermentation patterns of the two species are often the same. DNA relatedness between *Bifidobacterium boum* and *Bifidobacterium thermophilum* has been studied extensively (Scardovi et al., 1979b). DNA relatedness values of 36–74% have been reported between *Bifidobacterium boum* and *Bifidobacterium thermophilum* (Table 23).

8. **Bifidobacterium breve** Reuter 1963, 502[AL]

bre′ve. L. neut. adj. *breve* short.

The cell morphology is responsible for the designation of the specific epithet: the species encompasses organisms with the thinnest and shortest cells among bifids found in the human intestine (Figure 67, panel 8).

One hundred and six strains of *Bifidobacterium breve*, including a few that ferment arabinose and xylose, have been identified by DNA–DNA hybridization studies and their transaldolase and 6PGD isozymes were determined. Of these, 57% had unique zymograms and 25% displayed the same zymogram as *Bifidobacterium coryneforme*, a bifid found only in the intestine of the honey bee (Scardovi et al., 1979a).

The genome of *Bifidobacterium breve* UCC 2003 is the largest *Bifidobacterium* genome sequenced to date; it has roughly 47 kilobases (Leahy et al., 2005).

Source: the type strain was isolated from the feces of a human infant.

DNA G+C content (mol%): 58 (Bd).

Type strain: S1, ATCC 15700, DSM 20213, JCM 1192, NCIMB 702257.

Sequence accession no. (16S rRNA gene): M58731.

Additional comments: among bifids isolated from newborn infants that do not ferment pentoses, the rank of species was attributed to those fermenting D-mannitol and D-sorbitol. Two biovars, a and b, with differences towards melezitose fermentation were recognized. Serologically related strains isolated from breast-fed older infants and that did not ferment mannitol or sorbitol were referred to as a separate species, namely "*Bifidobacterium parvulorum*" (Reuter, 1963).

Strain S50 (=ATCC 15698), the type strain of "*Bifidobacterium parvulorum*" biovar a, "*Bifidobacterium parvulorum*" biovar b strain S17c (=ATCC 15699), and *Bifidobacterium breve* biovar b strain S46 (ATCC 15701) had 88, 94, and 86% DNA relatedness, respectively, to strain $S1^T$ (=ATCC 15700^T), the type strain of *Bifidobacterium breve* biovar a; other DNA relatedness tests proved the genetic identity of the two Reuters' species (Scardovi et al., 1971a). On the basis of DNA relatedness data, *Bifidobacterium breve* is more closely related to *Bifidobacterium longum* subsp. *infantis* and *Bifidobacterium longum* subsp. *longum* than to any other species of the genus (40–60% relatedness).

9. **Bifidobacterium catenulatum** Scardovi and Crociani 1974, 18[AL]

ca.te.nu.la′tum. L. n. *catenula* a small chain; L. neut. suff. *-atum* suffix used in adjectives meaning provided with; N.L. neut. adj. *catenulatum* having small chains.

Cells grown in TPY agar stabs are generally and characteristically arranged in chains of three, four, or more globular elements. The distal ends of the chains are usually tapered. Distinct branchings, club-like swellings, or spatula-like extremities are rare (Figure 67, panel 9). Anaerobic. CO_2 does not have any effect on O_2 sensitivity or anaerobic growth.

Most strains of *Bifidobacterium catenulatum* ferment D-sorbitol, but not D-mannitol, similar to *Bifidobacterium adolescentis* biovar c and *Bifidobacterium pseudocatenulatum* (see below), but they can be distinguished from the former because they ferment melezitose, and from the latter as they do not ferment starch (Table 22). Riboflavin and pantothenate are required for growth.

Source: found in feces of human adults and in sewage. The type strain was isolated from the feces of a human adult.

DNA G+C content (mol%): 54.7 ± 0.2 (T_m).

Type strain: B669, ATCC 27539, DSM 20103, JCM 1194, LMG 11043, NCIMB 702246.

Sequence accession no. (16S rRNA gene): M58732.

Additional comments: most strains show DNA relatedness to *Bifidobacterium adolescentis* (reference DNA from strain E298b, ATCC 15705, biovar c of Reuter) in the range 30–57% (Scardovi and Crociani, 1974). *Bifidobacterium catenulatum* should be considered, as should *Bifidobacterium pseudocatenulatum* (see below), to be more closely related to *Bifidobacterium adolescentis* than to any other species of the genus *Bifidobacterium* on this basis.

10. **Bifidobacterium choerinum** Scardovi, Trovatelli, Biavati and Zani 1979b, 307[AL]

choe.ri′num. N.L. neut. adj. *choerinum* (from Gr. adj. *khoireos*) pertaining to a pig.

Cells grown in TPY agar stabs are often short or coccoid and are similar to those of *Bifidobacterium pseudolongum* subsp. *globosum* (Figure 67, panel 10). In liquid medium, cells may be elongated to 10–12 µm, bent, with rounded or spatulated ends. Anaerobic. The effect of CO_2 is not detectable.

Strains of this species that ferment raffinose, but not L-arabinose, D-ribose, or D-sorbitol, cannot be distinguished from *Bifidobacterium boum* or *Bifidobacterium thermophilum* on this basis (Table 22).

Transaldolase and 6PGD isozymes are 3 and 4, respectively, a pattern unique among bifidobacteria. The species has a distinct PAGE protein pattern (Biavati et al., 1982).

Source: found in feces of piglets or occasionally in sewage. The type strain was isolated from the feces of a pig.

DNA G+C content (mol%): 66.3 ± 0.15 (T_m).

Type strain: Su806, ATCC 27686, DSM 20434, JCM 1212, LMG 10510.

Sequence accession no. (16S rRNA gene): D86186.

Additional comments: Bifidobacterium choerinum cannot be distinguished by its sugar fermentation pattern from either *Bifidobacterium thermophilum* biovar c (Mitsuoka, 1969) or from strains of *Bifidobacterium boum* that ferment D-lactose but not melezitose (Table 22). These three species are found frequently in the feces of piglets. However, transaldolase electrophoresis can be used to distinguish between them. The most anodal isozyme is that of *Bifidobacterium choerinum* (migration 100) and the least anodal is that of *Bifidobacterium thermophilum* (isozyme 8; migration 84); an intermediate form is shown by *Bifidobacterium boum* (isozyme 6; migration 90). Alternatively, PAGE patterns of soluble proteins can be used to distinguish between these taxa. The DNA of this species shows 26–57% and 37–62% relatedness to DNA of *Bifidobacterium pseudolongum* subsp. *globosum* and *Bifidobacterium pseudolongum* subsp. *pseudolongum*, respectively. An unexpected DNA relatedness value of 50% is observed between *Bifidobacterium choerinum* and *Bifidobacterium asteroides*.

11. **Bifidobacterium coryneforme** (*ex* Scardovi and Trovatelli 1969) Biavati, Scardovi and Moore 1982, 368[VP] (*Bifidobacterium coryneforme* Scardovi and Trovatelli 1969, 85)

co.ry.ne.for′me. Gr. n. *coryne* a club; L. neut. suff. *-forme* of the shape of; N.L. neut. adj. *coryniforme* club-shaped.

Grows poorly in TPY medium, but profusely in MRS medium. Cells grown in MRS agar stabs are short (1–1.5 µm long), often lanceolate, single, or in pairs, sometimes with short branches or simple knobs (Figure 67, panel 11). Radial groupings of cells are very rare and are formed under extreme growth conditions (Scardovi and Trovatelli, 1969). Anaerobic. Does not develop in slants inoculated under 90% air + 10% CO_2. CO_2 does not influence anaerobic growth on either solid or in liquid medium.

TABLE 23. DNA–DNA hybridization between *Bifidobacterium* species[a,b]

Competitor DNA from	Hybridization (%) to reference DNA from: *B. bifidum*	*B. longum* subsp. *longum*	*B. longum* subsp. *infantis*	*B. longum* subsp. *suis*	*B. breve*	*B. adolescentis*	*B. angulatum*	*B. catenulatum*	*B. pseudocatenulatum*	*B. dentium*	*B. gallicum*	*B. pseudolongum* subsp. *globosum*	*B. pseudolongum* subsp. *pseudolongum*

20	44			10				12	8	17	1–4	25	0	0	23	100

Aldolase is not detected in cell-free extracts. Hexose monophosphate dehydrogenases are present. Transaldolase and 6PGD isozyme patterns (6-6) are shared by some strains of *Bifidobacterium breve*. However, zymograms of 3-phosphoglyceraldehyde dehydrogenase (Scardovi et al., 1979a) and PAGE protein patterns are distinct (Biavati et al., 1982).

Source: strains assigned to this species have been isolated occasionally from the intestine of the honey bees *Apis mellifera* subsp. *mellifera* and *Apis mellifera* subsp. *caucasica*, from Germany (Bayern), Norway (Billingstad), England (Buckfast, Buckfastleigh), and Bulgaria. The type strain was isolated from the intestine of *Apis mellifera* subsp. *caucasica* from Norway.

DNA G+C content (mol%): not determined.

Type strain: C215, ATCC 25911, DSM 20216, JCM 5819, LMG 18911.

Sequence accession no. (16S rRNA gene): M58733.

Additional comments: Bifidobacterium coryneforme Scardovi and Trovatelli (1969) was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980). Its revival was proposed on the basis of its distinct electrophoretic cellular protein pattern and previously confirmed differential characteristics (Biavati et al., 1982). It is not related to other *Bifidobacterium* species, except *Bifidobacterium indicum*, on the basis of DNA relatedness. An interspecific DNA relatedness value of 60% has been reported (Scardovi et al., 1970).

12. **Bifidobacterium cuniculi** Scardovi, Trovatelli, Biavati and Zani 1979b, 307[AL]

cu.ni′cu.li. L. n. *cuniculus* rabbit; L. gen. n. *cuniculi* of the rabbit.

Cells grown in TPY agar stabs present a morphology that is very similar to that of *Bifidobacterium pseudolongum* subsp. *globosum* and *Bifidobacterium pseudolongum* subsp. *pseudolongum*. However, the short knobs or protuberances often in the center of the cells are rarely seen in other *Bifidobacterium* species (Figure 67, panel 12). Highly anaerobic. CO_2 has no effect on O_2 sensitivity or anaerobic growth.

D-Lactose and raffinose are characteristically not fermented. D-Fructose is regularly fermented, but only in prereduced media.

Transaldolase isozyme 1 and 6PGD isozyme 4 were found in seven strains studied by Scardovi et al. (1979a). This 1-4 pattern is unique among bifidobacteria.

Source: found in feces of adult rabbits. The type strain was isolated from the feces of a rabbit.

DNA G+C content (mol%): 64.1 ± 0.35 (T_m).

Type strain: RA93, ATCC 27916, DSM 20435, JCM 1213, LMG 10738.

Sequence accession no. (16S rRNA gene): M58734.

Additional comments: Bifidobacterium cuniculi can be distinguished easily from the morphologically similar taxa *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium pseudolongum* subsp. *pseudolongum*, and *Bifidobacterium animalis* subsp. *lactis*, which are also frequently found in rabbit feces, by its inability to ferment D-lactose, raffinose, and D-ribose. The same fermentation pattern can be used to distinguish *Bifidobacterium cuniculi* from the morphologically diverse *Bifidobacterium magnum*, another species isolated from the same source.

The DNA of the species is 50–67% related to that of *Bifidobacterium pseudolongum* subsp. *globosum* [reference strain RU 230 (=ATCC 25864)], but far less related to *Bifidobacterium pseudolongum* subsp. *pseudolongum* and other species of the genus *Bifidobacterium*.

13. **Bifidobacterium dentium** Scardovi and Crociani 1974, 18[AL]

den′ti.um. L. masc. n. *dens* tooth; L. pl. gen. n. *dentium* of teeth.

Cells grown in TPY agar show a general morphology resembling that of *Bifidobacterium infantis* (Figure 67, panel 13); hence, they are without any characteristic appearance. Anaerobic. CO_2 does not affect sensitivity to O_2 or anaerobic growth. Requires pantothenate and riboflavin for growth, similar to *Bifidobacterium angulatum* and *Bifidobacterium catenulatum*.

Source: found in human dental caries and plaque (Modesto et al., 2006). The type strain was isolated from human dental caries.

DNA G+C content (mol%): 61.2 ± 0.4 (T_m).

Type strain: B764, ATCC 27534, DSM 20436, JCM 1195, LMG 11045, NCIMB 702243.

Sequence accession no. (16S rRNA gene): D86183.

Additional comments: Bifidobacterium dentium cannot be distinguished phenotypically from *Bifidobacterium adolescentis* biovars b and d (strains not fermenting sorbitol; see Table 22). The distinction between these two species should be based either on transaldolase isozymes or on electrophoresis of total cellular proteins patterns (see *Bifidobacterium adolescentis*).

A number of bifid strains isolated from human dental caries, feces of human adults, and from the human vagina were assigned to *Bifidobacterium adolescentis* using phenotypic properties, but were subsequently recognized as forming a distinct “dentium” DNA homology group together with strains isolated from the oral cavity (Beerens et al., 1957) and strain 3859, which was labeled as *Bifidobacterium appendicitis*. *Bifidobacterium dentium* (Table 23) is most closely related to *Bifidobacterium adolescentis* on the basis of DNA relatedness, but is less related or unrelated to other *Bifidobacterium* species. DNA of “*Actinomyces eriksonii*” ATCC 15423 and ATCC 15424 are completely homologous to that of *Bifidobacterium dentium* reference strain B764^T (Scardovi et al., 1979a).

A study on the presence and distribution in human plaque and dental caries of *Bifidobacterium dentium*, *Scardovia inopinata*, and *Parascardovia denticolens*, which all belong to the family *Bifidobacteriaceae*, showed that *Scardovia inopinata* was the species most frequently isolated in dental caries, whereas *Bifidobacterium dentium* was more numerous in dental plaque. The prevalence of *Parascardovia denticolens* was similar in the two habitats (Modesto et al., 2006).

14. **Bifidobacterium gallicum** Lauer 1990, 100[VP]

gal′li.cum. L. neut. adj. *gallicum* of or belonging to the Gauls, although ethnic relationships to the French remains speculative.

Short rods with rounded ends, generally 0.7–0.9 µm by 1.5–3 µm, mostly arranged in pairs or short chains when grown in liquid culture (Figure 67, panel 14). Irregular elongations and swellings occur in cells obtained from colony growth. A slimy, capsule-like material is excreted in complex media containing meat extract, bacteriological peptone, and fermentable carbohydrates. Colonies are whitish, opaque, round, entire, and have a soft consistency. Optimal growth is at 37–39°C. Growth does not occur below 30°C or at 45°C and above. Grows at pH 5.0–8.0; optimal growth occurs between pH 6.0 and 7.0.

L-Arabinose, dextrin, D-fructose, D-galactose, D-glucose, glycogen, maltose, D-ribose, salicin (slowly), starch, sucrose, and D-xylose are fermented, but not D-arabinose, D-gluconate, glycerol, inulin, D-mannitol, D-mannose, melezitose, *myo*-inositol, raffinose, L-rhamnose, D-sorbitol, trehalose, or L-xylose.

The following enzyme activities are present in cell-free extracts: fructose-6-phosphate, L-(+)-lactate dehydrogenase (NAD-dependent and allosterically regulated by fructose 1,6-diphosphate), transaldolase, and xylulose-5-phosphate phosphoketolases. There is no fructose-1,6-diphosphate aldolase activity. Relative electrophoretic mobilities are: lactate dehydrogenase (R_{LDH}), 1.10 relative to rabbit-iso-I lactate dehydrogenase of muscle; and transaldolase (R_{TA}), 1.65 relative to type X transaldolase of yeast.

The peptidoglycan type is L-Lys–L-Ala–L-Ser (A3α); some lysine moieties are replaced to a variable degree by ornithine. The cell-wall polysaccharide comprises a galactan polymer of unknown structure. Minor amounts of rhamnose may be found in addition to galactose after growth on less complex media.

Source: habitat is not known. The type, and only strain, was isolated from human feces.

DNA G+C content (mol%): 61 (T_m).

Type strain: P6, ATCC 49850, DSM 20093, JCM 8224, LMG 11596.

Sequence accession no. (16S rRNA gene): D86189.

15. **Bifidobacterium gallinarum** Watabe, Benno and Mitsuoka 1983, 130[VP]

gal.li.na′rum. L. n. *gallina* hen; L. gen. pl. n. *gallinarum* of hens.

Slightly curved, short rods (0.5–1.0 µm wide by 1.0–2.5 µm long) with tapered ends, usually arranged singly or in short chains (Figure 67, panel 15). Swellings or club-shaped cells are frequently observed. In older liquid cultures, some cells have short branches. Surface colonies on BL agar (Mitsuoka et al., 1965) after 2 d of anaerobic incubation are punctiform to 1 mm in diameter, circular, entire, flat to convex, gray to grayish white, transparent to translucent, and glistening. Strictly anaerobic. Gelatin is not liquefied. Gas is not formed from fructose or glucose. Fermentation products from fructose or glucose are lactic acid and acetic acid in a molar ratio of 1:4.0 in EG broth (Mitsuoka et al., 1965); butyric and propionic acids are not formed. Final pH of glucose or fructose broth is 4.5–5.1.

Acid is produced from amygdalin, dextrin, esculin, D-fructose, inulin, maltose, melibiose, raffinose, D-ribose, salicin, sucrose, and D-xylose. L-Arabinose, cellobiose, D-galactose, D-glucose, D-lactose, D-mannose, methyl α-glucoside, and trehalose are usually fermented, but not glycogen, inositol, D-mannitol, L-rhamnose, D-sorbitol, or starch. Melezitose is not usually fermented. Nitrate is not reduced and neither indole nor hydrogen sulfide are produced. Ammonia is not produced from arginine. Litmus milk is usually acidified.

Source: the type strain was isolated from chicken cecum.

DNA G+C content (mol%): 65.7 ± 1.5 (T_m).

Type strain: Ch206-5, ATCC 33777, DSM 20670, JCM 6291, LMG 11586.

Sequence accession no. (16S rRNA gene): D86191.

Additional comments: DNA relatedness values with *Bifidobacterium pullorum* and *Bifidobacterium saeculare* are higher than those with other *Bifidobacterium* species (Biavati et al., 1991).

16. **Bifidobacterium indicum** Scardovi and Trovatelli 1969, 84[AL]

in′di.cum. L. neut. adj. *indicum* of India, Indian, named after the specific epithet of *Apis indica* F.

Cells grown in TPY agar stabs are generally short, occur in pairs, often in an angular disposition, and are more or less globular, sometimes suggesting a minute morphovar of *Bifidobacterium pseudolongum* subsp. *globosum* (Figure 67, panel 16). Some strains have slender and longer cells, but star-like clusters of cells never occur. Cells grown on gluconate are extremely small and regular in shape (Sgorbati et al., 1970). Colonies do not have the consistency of those of *Bifidobacterium asteroides*. Cells grown in liquid media do not adhere to the walls and sediment very slowly. Oxygen tolerance is similar to that of *Bifidobacterium asteroides*. CO_2 is required for aerobic growth, whereas the effect of CO_2 is equivocal for anaerobic growth. H_2O_2 is decomposed only by cells grown in 90% air + 10% CO_2 in the presence of hemin.

Cell-free extracts are fructose-bisphosphate aldolase-negative, but possess hexose monophosphate dehydrogenases. G6PDH uses both $NADP^+$ and NAD^+, whereas only $NADP^+$ is effective in 6-phosphogluconate dehydrogenation (Scardovi and Trovatelli, 1969). A total of 122 strains from different sources (Japan, Malaysia, Philippines) was examined for their transaldolase and 6PGD zymograms. Starch gel electrophoresis showed the presence of isozymes 4 and 7, respectively. Most strains isolated from *Apis dorsata* possess a transaldolase isozyme (number 7) that differs from that found in strains isolated from the intestine of *Apis cerana* subsp. *indica* (number 9) (Scardovi et al., 1979a).

Extrachromosomal elements were found in 73 out of 106 strains, 57% of which had a 22 MDa plasmid, whereas 33% showed a two-banded pattern at 2.0 and 3.5 MDa (Sgorbati et al., 1982). The cellular functions encoded by these plasmids are not known.

Source: the type strain was isolated from the intestine of *Apis cerana* subsp. *indica* from Malaysia.

DNA G+C content (mol%): 60 (T_m).

Type strain: C 410, ATCC 25912, DSM 20214, JCM 1302, LMG 11587.

Sequence accession no. (16S rRNA gene): D86188.

17. **Bifidobacterium longum** Reuter 1963, 502[AL]

lon.gum. L. neut. adj. *longum* long.

D-Galactose, D-lactose, maltose, melibiose, raffinose, and sucrose are fermented, but not gluconate, D-mannitol, salicin, D-sorbitol, starch, or trehalose. Variable responses are shown for L-arabinose, cellobiose, D-fructose, inulin, D-mannose, melezitose, and D-xylose. Cell-wall amino acids consist of L-Orn–L-Ser–L-Ala–L-Thr–L-Ala.

Source: a similar ecological distribution is shared by *Bifidobacterium longum* subsp. *longum* and *Bifidobacterium longum* subsp. *infantis*, which are particularly found in the gastrointestinal tracts of humans and infants, respectively; *Bifidobacterium longum* subsp. *suis* is typically found in the pig gastrointestinal tract.

Type strain: see subspecies below.

Additional comments: Bifidobacterium longum, *Bifidobacterium infantis*, and *Bifidobacterium suis* strains have DNA relatedness values around or above 70% (Bahaka et al., 1993; Lauer and Kandler, 1983; Scardovi et al., 1979a). Phylogenetic analyses of the genus *Bifidobacterium* based on 16S rRNA gene sequences (Miyake et al., 1998) and a heat-shock protein (Jian et al., 2001) also showed *Bifidobacterium infantis*, *Bifidobacterium longum*, and *Bifidobacterium suis* to be closely related. On the basis of these data, Sakata et al. (2002) placed the three taxa into the single species *Bifidobacterium longum* and established the three biotypes “longum”, “infantis”, and “suis” for strains belonging to the former species. However, a variety of other genotypic techniques, including ribotyping, ARDRA, BOX-PCR, PCR-DGGE, randomly amplified polymorphic DNA-PCR and comparison of *ldh*, *recA*, and *tuf* gene sequences (Masco et al., 2003; Matsuki et al., 1998; Requena et al., 2002; Roy et al., 1996; Sakata et al., 2006; Ventura et al., 2003), and plasmid profiling (Sgorbati et al., 1982), clearly distinguished between *Bifidobacterium longum*, *Bifidobacterium infantis*, and *Bifidobacterium suis*, as do carbohydrate fermentation patterns (Crociani et al., 1994; Sakata et al., 2002; Scardovi, 1986), starch hydrolysis (Scardovi et al., 1979a), and PAGE analysis (Biavati et al., 1982; Roy et al., 1994).

The genotypic and phenotypic variations described above revealed considerable differences between members of the three former species and supported the description of “*Bifidobacterium longum*”, “*Bifidobacterium infantis*”, and “*Bifidobacterium suis*” as subspecies of *Bifidobacterium longum*. Consequently, Mattarelli et al. (2008) described three *Bifidobacterium longum* subspecies: *Bifidobacterium longum* subsp. *longum* subsp. nov., *Bifidobacterium longum* subsp. *infantis* comb. nov. and *Bifidobacterium longum* subsp. *suis* comb. nov. The “International Committee on Systematic Bacteriology Subcommittee on *Bifidobacterium*, *Lactobacillus* and related organisms” supported this proposal (Klein, 2006).

17a. **Bifidobacterium longum subsp. longum** (Reuter 1963) Mattarelli, Bonaparte, Pot and Biavati 2008, 770[VP] (*Bifidobacterium longum* Reuter 1963, 502)

lon.gum. L. neut. adj. *longum* long.

Most strains show very elongated and relatively thin cellular elements with slightly irregular contours and rare branching on TPY agar (Figure 67, panel 17a). In TPY broth, most strains develop a uniform turbidity; clearing is slow and the sediment is viscous.

Two biovars can be distinguished. Biovar a [E194 (variant a)^{T} (=ATCC 15707^{T})] is more frequent in human adults and slowly ferments mannose, whereas biovar b [S3 (variant b) (=ATCC 15708)] is more frequent in neonates and is mannose-negative (Reuter, 1963).

Bifidobacterium longum is apparently the only species among those usually found in human feces that possesses a large variety of plasmids (Sgorbati et al., 1982).

Source: the type strain was isolated from the feces of an adult human.

DNA G+C content (mol%): 61 (T_m).

Type strain: E194b (variant a), ATCC 15707, DSM 20219, JCM 1217, NCIMB 702259, LMG 13197.

Sequence accession no. (16S rRNA gene): M58739.

Additional comments: Bifidobacterium longum subsp. *longum* NCC2705 (GenBank accession no. for genome sequence AE014295) was the first *Bifidobacterium* strain to be completely sequenced. Sequencing the DNA of this strain revealed much about its metabolic diversity and generated insights into other members of the genus (Schell et al., 2002). Bioinformatic analysis revealed several physiological traits that partially explain the successful adaptation of this organism to the colon. An unexpectedly large number of the predicted proteins appear to be specialized for the catabolism of a variety of oligosaccharides, some possibly released by rare or novel glycosyl hydrolases acting on “nondigestible” plant polymers or host-derived glycoproteins and glycoconjugates. The genome of *Bifidobacterium longum* DJO10A has also been completely sequenced (GenBank accession no. CP000605) (Lee et al., 2008).

In 1969, Mitsuoka described “*Bifidobacterium longum* subsp. *animalis*” with biovars a and b, which can be distinguished from *Bifidobacterium longum* subsp. *longum* on the basis of melezitose and D-mannose fermentation, DNA relatedness, and by their ecology; they have been subsequently recognized as belonging to *Bifidobacterium animalis* [biovar a, R101-8^{T} (=ATCC 25527^{T}), from rat feces (Scardovi and Trovatelli, 1974)] and *Bifidobacterium pseudolongum* subsp. *pseudolongum* [biovar b, C10-45 (=DSM 20097), from calf feces (Scardovi et al., 1971b)], respectively.

17b. **Bifidobacterium longum subsp. infantis** (Reuter 1963) Mattarelli, Bonaparte, Pot and Biavati 2008, 770[VP] (*Bifidobacterium infantis* Reuter 1963, 502)

in.fan′tis. L. gen. n. *infantis* of an infant.

The cellular morphology does not present any specific traits as it is similar to that of many other *Bifidobacterium* species (Figure 67, panel 17b). Pentoses are not fermented.

Source: isolated as predominant forms from breast-fed infant feces. The type strain was isolated from the feces of a human infant.

DNA G+C content (mol%): 60.5 (T_m).

Type strain: S12, ATCC 15697, DSM 20088, JCM 1222, NCIMB 702205.

Sequence accession no. (16S rRNA gene): X70974.

Additional comments: the genome of *Bifidobacterium longum* subsp. *infantis* ATCC 15697[T] (GenBank accession no. CP001095) has been completely sequenced (Sela et al., 2008); it is the biggest bifidobacterial genome sequenced so far. Reuter (1963) proposed the name *Bifidobacterium infantis* for biochemical and seroliquid distinct strains isolated from infant feces. Bifid strains from the same source but with the ability to ferment D-xylose were separated and classified into two additional species, namely *Bifidobacterium liberorum* and *Bifidobacterium lactentis*, based on differences in other fermented sugars (Reuter, 1963). DNA relatedness data subsequently showed that these species were identical to *Bifidobacterium infantis* (Scardovi et al., 1971b).

Bifidobacterium parabifidum (Weiss and Rettger) Kandler and Lauer (1974) is considered here to be a synonym of *Bifidobacterium infantis* because strain ATCC 17930 [Timberlain strain isolated by Norris et al. (1950) and studied by Pine and Howell (1956), under the label 308]: (a) shows 82% DNA relatedness to ATCC 27920, one of the reference strains of *Bifidobacterium infantis*; (b) displays 76% DNA relatedness to ATCC 15707[T], the type strain of *Bifidobacterium longum*; and (c) possesses the protein pattern of *Bifidobacterium infantis* (Biavati et al., 1982).

17c. **Bifidobacterium longum subsp. suis** (Matteuzzi, Crociani, Zani and Trovatelli 1971) Mattarelli, Bonaparte, Pot and Biavati 2008, 771[VP] (*Bifidobacterium suis* Matteuzzi, Crociani, Zani and Trovatelli 1971, 393)

su′is. L. gen. n. *suis* of a hog.

Cells grown in TPY agar stabs show a similar morphology to those of many other *Bifidobacterium* species (Figure 67, panel 17c). Anaerobic. CO_2 does not affect O_2 sensitivity or anaerobic growth. Riboflavin is the only required growth factor.

Cell-free extracts possess fructose-bisphosphate aldolase and hexose monophosphate dehydrogenases. Most strains show a constitutive urease activity, which is not influenced by urea or organic nitrogen sources. Half of the strains tested share the transaldolase-6PGD isozyme electrophoretic pattern 6-5 with some *Bifidobacterium longum* subsp. *longum* and *Bifidobacterium longum* subsp. *infantis* strains; others display a pattern (6-8) that is common in *Bifidobacterium longum* subsp. *longum* (Scardovi et al., 1979a). The PAGE protein pattern is quite distinct from that of other *Bifidobacterium* species (Biavati et al., 1982).

Source: only found in the feces of piglets. The type strain was isolated from feces of a piglet.

DNA G+C content (mol%): 62 (T_m).

Type strain: SU 859, ATCC 27533, DSM 20211, JCM 1269.

Sequence accession no. (16S rRNA gene): M58743.

Additional comments: Bifidobacterium longum subsp. *suis* can be readily distinguished from other bifid species commonly found in pig feces, namely *Bifidobacterium boum*, *Bifidobacterium choerinum*, *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium pseudolongum* subsp. *pseudolongum*, and *Bifidobacterium thermophilum* on the basis of carbohydrate fermentation. The latter three species do not ferment arabinose or xylose, whereas *Bifidobacterium longum* subsp. *suis* does; the former two species ferment starch, but *Bifidobacterium longum* subsp. *suis* does not (Table 22; Zani et al., 1974).

18. **Bifidobacterium magnum** Scardovi and Zani 1974, 31[AL]

mag′num. L. neut. adj. *magnum* large, great.

Cells grown in TPY agar are usually characteristically long and thick, with irregular contours, measuring 2 × 10–20 µm and occurring frequently in aggregates (Figure 67, panel 18). Anaerobic. CO_2 does not affect O_2 sensitivity or anaerobic growth. The only acidophilic *Bifidobacterium* species; its optimal pH for growth is 5.3–5.5; growth is retarded at pH 5.0 and 5.9 and it does not grow at pH 4.2 or 7.0 (after 2 d). Sparse growth in TPY medium without Tween 80, as this component is highly stimulatory (Scardovi and Zani, 1974).

Fructose-bisphosphate aldolase is present in cell-free extracts (4–5 mU/mg proteins). $NADP^+$-dependent G6PDH is measurable. Aldolase is spot-stainable on electrophoresis (Scardovi and Sgorbati, 1974). The isozyme pattern 5-7 (transaldolase and 6PGD types, respectively) is unique among bifidobacteria (Scardovi et al., 1979a). The PAGE protein pattern is clearly distinct from that of any other *Bifidobacterium* species (Biavati et al., 1982).

Source: strains, including the type strain, found in the feces of rabbits.

DNA G+C content (mol%): 60.0 ± 0.6 (T_m).

Type strain: RA3, ATCC 27540, DSM 20222, JCM 1218, LMG 11591.

Sequence accession no. (16S rRNA gene): M58740.

Additional comments: the recognition of *Bifidobacterium magnum* should not be based solely on the unusually large dimensions of its cells. Fermentation of lactose and starch are useful in differentiating *Bifidobacterium magnum* from the “animal” species *Bifidobacterium animalis*, *Bifidobacterium pseudolongum* subsp. *globosum*, *Bifidobacterium pseudolongum* subsp. *pseudolongum*, and *Bifidobacterium pullorum*, which also ferment pentoses. *Bifidobacterium magnum* ferments lactose, but not starch, whereas the other species ferment either both or neither of these sugars (*Bifidobacterium pullorum*). *Bifidobacterium magnum* can be distinguished from the human species *Bifidobacterium longum* subsp. *infantis* and *Bifidobacterium longum* subsp. *longum* only by virtue of having different 6PGD isozymes. The transaldolase isozyme of *Bifidobacterium magnum* is shared by *Bifidobacterium infantis* (number 5). Alternatively, PAGE analysis can be used to separate these taxa.

19. **Bifidobacterium merycicum** Biavati and Mattarelli 1991, 167[VP]

me.ry′ci.cum. Gr. n. *meryx* (implied by verb *merykazo*) rumen; N.L. neut. adj. *merycicum* pertaining to the rumen.

Irregularly shaped rods that are 2.0–5.0 µm long and are sometimes arranged in angled pairs (Figure 67, panel 19). Surface colonies on TPY agar are soft, smooth, convex, circular with entire margins, cream to white, and glistening. Carbon dioxide has no effect on oxygen sensitivity, but it enhances anaerobic growth. The optimal temperature for growth is 38–42°C; growth does not occur below 25°C or above 45°C. The optimal initial pH for growth is 6.5–6.9; growth is delayed at pH 6.3 and 7.2, and does not occur at pH 4.5 or 8.

L-Arabinose, dextrin, D-fructose (weak), D-galactose, D-glucose, D-lactose, maltose, melibiose, raffinose, D-ribose, starch, sucrose, and D-xylose are all fermented, but glycerin, gluconate, lactate, D-mannitol, D-mannose, melezitose, L-rhamnose, D-sorbitol, and trehalose are not. Salicin and inulin are either not fermented or are occasionally fermented slowly. Cellobiose fermentation is variable.

Source: strains, including type strain, isolated from bovine rumen.

DNA G+C content (mol%): 59 (T_m).

Type strain: Ru915B, ATCC 49391, DSM 6492, JCM 8219, LMG 11341.

Sequence accession no. (16S rRNA gene): D86192.

20. **Bifidobacterium minimum** Biavati, Scardovi and Moore 1982, 368[VP]

min′i.mum. L. neut. adj. sup. *minimum* the least.

Cells grown in TPY agar stabs are characteristically very small (0.3 × 1.3–1.5 µm) with tapered ends and sometimes irregularly branched (Figure 67, panel 20). This morphology resembles that of *Bifidobacterium asteroides*, but star-like aggregates, characteristic for that species, are absent. Anaerobic. CO_2 has no affect on O_2 sensitivity or anaerobic growth. Sugars fermented include D-fructose, D-glucose, maltose, starch, and sucrose.

Cells possess the least anodal form of transaldolase among bifidobacteria (pattern 10, i.e. migration 66, whereas the most anodal isozyme, pattern 1, in *Bifidobacterium cuniculi*, migrates 100) (Scardovi et al., 1979a). Does not contain aldolase or G6PDH. The interpeptide bridge of the cell-wall peptidoglycan is Lys–Ser, which is unique amongst bifidobacteria. The PAGE protein pattern is distinct.

Source: the type strain was isolated from wastewater (sewage). Some isolates identified as *Bifidobacterium minimum* have been found in the cecum of pigs (Simpson et al., 2003); this was the first time that this species had been found in a natural habitat. These isolates had a type F PFGE profile.

DNA G+C content (mol%): 61.5 (T_m).

Type strain: F392, ATCC 27538, DSM 20102, JCM 5821, LMG 11592.

Sequence accession no. (16S rRNA gene): M59741.

Additional comments: this taxon was described previously and referred to as the "*minimum*" DNA homology group. It consisted of two strains isolated from sewage (Scardovi and Trovatelli, 1974).

21. **Bifidobacterium mongoliense** Watanabe, Makino, Sasamoto, Kudo, Fujimoto and Demberel 2009, 1539[VP]

mon.go.li.en′se. N.L. neut. adj. *mongoliense* pertaining to Mongolia, from where the type strain was isolated.

Cells grown in modified GAM broth are rods of various shapes, 0.4–0.6 × 0.8–2 µm, with rounded or tapered ends, sometimes curved, swollen, and branched (Figure 67, panel 21). Pinpoint colonies (0.2–0.4 mm in diameter) are formed under aerobic condition after 2 d incubation at 30°C. After anaerobic growth at 30°C for 5–6 d, colonies on modified GAM agar are 2–3 mm in diameter, convex, white, opaque, smooth, and circular with entire edges. Facultatively anaerobic. Catalase- and oxidase-negative. The temperature range for growth is 15–35°C; growth does not occur at 10°C or 40°C. The optimal temperature for growth is 25–30°C. Grows between pH 4.5 and 8.0, with optimum growth at pH 6.5–7.0.

Acid is produced from L-arabinose, D-galactose, D-glucose, glycogen, maltose, D-lactose, melibiose, methyl α-D-glucopyranoside, raffinose, starch, sucrose, and turanose, but not from *N*-acetylglucosamine, D-adonitol, D-arabinose, D- or L-arabitol, dulcitol, erythritol, D-fructose, D- or L-fucose, glycerol, inositol, inulin, 2- or 5-keto-gluconate, D-lyxose, D-mannitol, D-mannose, melezitose, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, L-rhamnose, D-sorbitol, L-sorbose, D-tagatose, -trehalose, xylitol, or D- or L-xylose. Acid production from amygdalin, arbutin, cellobiose, β-gentiobiose, gluconate, D-ribose, and salicin is strain-dependent. Esculin is hydrolyzed.

Peptidoglycan structure is L-Lys–D-Asp type in the presence of Lys, Glu, Ala, and Asp.

Source: strains, including the type strain, were isolated from airag, a traditional fermented mare's milk, which was collected in Umnugobi and Uburhangai Provinces in Mongolia in 2004.

DNA G+C content (mol%): 61.1 (T_m).

Type strain: YIT 10443, JCM 15461, DSM 21395.

Sequence accession no. (16S rRNA gene): AB433856.

Additional comments: phylogenetic analysis of the 16S rRNA gene sequence places *Bifidobacterium mongoliense* in the *Bifidobacterium minimum* subgroup of bifidobacteria.

22. **Bifidobacterium pseudocatenulatum** Scardovi, Trovatelli, Biavati and Zani 1979b, 309[AL]

pseu.do.ca.te.nu.la′tum. Gr. adj. *pseudês* false; N.L. neut. adj. *catenulatum* specific epithet; N.L. neut. adj. *pseudocatenulatum* the false (*Bifidobacterium*) *catenulatum*.

Cell morphology is one of the most variable amongst the bifidobacteria and highly diverse traits reflect the origin of the strains (Figure 67, panel 22). Anaerobic. CO_2 does not affect O_2 sensitivity or anaerobic growth. Nicotinic acid, pantothenate, and riboflavin are required for growth. The structure of the interpeptide bridge of the cell-wall peptidoglycan is shared by *Bifidobacterium catenulatum* and *Bifidobacterium angulatum* (Table 21).

Source: found abundantly in sewage, in the feces of breast- and bottle-fed infants, and in those of suckling calves. The type strain was isolated from feces of a human infant.

DNA G+C content (mol%): 57.5 (T_m).

Type strain: B1279, ATCC 27919, DSM 20438, JCM 1200, LMG 10505.

Sequence accession no. (16S rRNA gene): M84785.

Additional comments: there is no doubt that *Bifidobacterium catenulatum* and *Bifidobacterium pseudocatenulatum* are closely related species as indicated by DNA hybridization data. However, the G+C content of their DNA differs by 3 mol% (Table 21). None of the strains shown genetically to be *Bifidobacterium catenulatum* ferment mannose or starch, whereas strains recognized by DNA hybridization as *Bifidobacterium pseudocatenulatum* ferment these carbohydrates. Unlike *Bifidobacterium pseudocatenulatum, Bifidobacterium catenulatum*

does not require nicotinic acid for growth. Furthermore, *Bifidobacterium catenulatum* has never been isolated from the feces of suckling calves.

When 41 strains of *Bifidobacterium catenulatum* and 120 strains of *Bifidobacterium pseudocatenulatum* were studied for their transaldolase and 6PGD isozyme content, the isozymes of the two species were found to migrate very differently (Table 21). The few *Bifidobacterium pseudocatenulatum* strains (7 out of 120) that possessed a transaldolase that was electrophoretically identical to that of *Bifidobacterium catenulatum* (number 5) displayed a much more anodal 6PGD isozyme (Table 21). Although some data suggest the existence of "intermediate" strains (Scardovi et al., 1979b), like those found between *Bifidobacterium longum* subsp. *longum* and *Bifidobacterium longum* subsp. *infantis* (see *Bifidobacterium longum*), and although PAGE analysis give uncertain results (Biavati et al., 1982), it is advisable at present to maintain the rank of species for these two taxa.

Sorbitol is fermented by all strains found in the feces of infants and by 50% of those present in calf feces. The sorbitol-fermenting strains can be distinguished from *Bifidobacterium adolescentis* strains as they are melezitose-negative and from *Bifidobacterium catenulatum* as they invariably ferment starch. The sorbitol-negative strains (so far found only in calf feces) can be distinguished from *Bifidobacterium pseudolongum* subsp. *globosum* and *Bifidobacterium pseudolongum* subsp. *pseudolongum* strains, which are also found in calf feces, and from *Bifidobacterium angulatum*, not only on the basis of a different morphology, but also by means of their transaldolase zymogram (Table 21).

The DNA of this species is 46–88% related to that of *Bifidobacterium catenulatum*, but is virtually unrelated to that of any other *Bifidobacterium* species (Table 21; Scardovi et al., 1979b).

23. **Bifidobacterium pseudolongum** Mitsuoka 1969, 60[AL]

pseu.do.long′um. Gr. adj. *pseudês* false; L. neut. adj. *longum* specific epithet; N.L. neut. adj. *pseudolongum* false (*Bifidobacterium*) *longum*.

Cells grown anaerobically in TPY agar are generally short, coccoid, or almost spherical to curved or tapered, arranged singly, doubly or, rarely, in short chains (Figure 67, panels 23a and 23b). This morphology does not change with strain or source. Only cells grown in air + CO_2 have bifurcations or short cross-branchings, often with enlarged ends (Scardovi et al., 1969). The interpeptide bridge of the cell-wall peptidoglycan is L-Orn(L-Lys)–L-Ala$_{2–3}$.

Because of the genetic and phenotypic similarity between *Bifidobacterium pseudolongum* (Mitsuoka, 1969) and *Bifidobacterium globosum* (Biavati et al., 1982), these two species have been rearranged taxonomically as subspecies: *Bifidobacterium pseudolongum* subsp. *pseudolongum* and *Bifidobacterium pseudolongum* subsp. *globosum* (Yaeshima et al., 1992b). The two subspecies share a similar ecological distribution, but *Bifidobacterium pseudolongum* subsp. *globosum* is found mainly in the rumen and intestine of ruminants, whereas no strain isolated from the rumen has been assigned to *Bifidobacterium pseudolongum* subsp. *pseudolongum*.

23a. **Bifidobacterium pseudolongum subsp. pseudolongum** (Mitsuoka 1969) Yaeshima, Fujisawa and Mitsuoka 1992a, 656[VP] (Effective publication: Yaeshima, Fujisawa and Mitsuoka 1992b, 385; *Bifidobacterium pseudolongum* Mitsuoka 1969, 60.)

pseu.do.long′um. Gr. adj. *pseudês* false; L. neut. adj. *longum* specific epithet; N.L. neut. adj. *pseudolongum* false (*Bifidobacterium*) *longum*.

Four biovars (a, b, c, and d) are recognized on the basis of differences in the fermentation of cellobiose, D-lactose, D-mannose, and melezitose. The effect of O_2 and CO_2 on growth has not been studied in detail. Requirements for growth factors are unknown. Growth in the presence of 4.5% sodium malate at 30°C is positive or weakly positive (Yaeshima et al., 1992b).

Dextrin, D-galactose, D-glucose, D-lactose, maltose, melibiose, methyl α-glucoside, raffinose, D-ribose, and sucrose are fermented, but not amygdalin, esculin, sodium gluconate, inositol, inulin, D-mannitol, D-mannose, melezitose, L-rhamnose, D-sorbitol, or trehalose. Cellobiose fermentation is variable.

Cells were not examined for the presence of fructose-bisphosphate aldolase or G6PDH. Using electrophoresis, the type strain PNC-2-9G^T (=ATCC 25526^T, biovar a), strain 29-Sr-T representing biovar e, and strain Mo-2-10 representing biovar d, all display transaldolase isozyme 2 and 6PGD isozyme 7, i.e. a pattern identical to that possessed only by two *Bifidobacterium pseudolongum* subsp. *globosum* strains of the 103 studied (Table 21; Scardovi et al., 1979a). PAGE protein patterns of some strains, including strain ATCC 25526^T, are clearly distinct from those of *Bifidobacterium pseudolongum* subsp. *globosum* (Biavati et al., 1982). Plasmids were not detected in the three strains studied (Sgorbati et al., 1982).

Source: isolated from the feces of bulls, calves, chickens, dogs, guinea pigs, hamsters, pigs, and rats. The type strain was isolated from pig feces.

DNA G+C content (mol%): 64.8 ± 0.7 (T_m).

Type strain: PNC-2-9G, ATCC 25526, DSM 20099, JCM 1205, LMG 11571, NCIMB 702244.

Sequence accession no. (16S rRNA gene): D86195.

Additional comments: DNA relatedness studies show that *Bifidobacterium pseudolongum* subsp. *pseudolongum* is 45–70% related to *Bifidobacterium pseudolongum* subsp. *globosum* and 10–15% related to *Bifidobacterium cuniculi* (Scardovi et al., 1971b; Yaeshima et al., 1992b). The Mitsuoka strain C10-45 ("*Bifidobacterium longum* subsp. *animalis*" biotype b; Mitsuoka, 1969) is completely homologous to strain Mo-2-10, a representative of biovar d of *Bifidobacterium pseudolongum* subsp. *pseudolongum* (Scardovi et al., 1971b).

Mitsuoka (1969) recognized that bifid strains isolated from a variety of animals belonged to this species. The strains fermented arabinose, glycogen, starch, and xylose and slowly fermented fructose, thereby differing from strains of *Bifidobacterium thermophilum* isolated from the same animal sources (Mitsuoka, 1969).

23b. **Bifidobacterium pseudolongum subsp. globosum** (Scardovi, Trovatelli, Crociani and Sgorbati 1969) Yaeshima, Fujisawa and Mitsuoka 1992a, 656[VP] (Effective publication: Yaeshima, Fujisawa and Mitsuoka 1992b, 385; *Bifidobacterium globosum*

Scardovi, Trovatelli, Crociani and Sgorbati 1969, 290; *Bifidobacterium globosum* Biavati, Scardovi and Moore 1982, 368.)

glo.bo′sum. L. neut. adj. *globosum* round as a ball, spherical, globular.

Anaerobic aerotolerant organism. CO_2 does not affect anaerobic growth, but permits growth under high O_2 tensions. Grows in 90% air + 10% CO_2. Aerobically grown cells do not show catalase or pseudocatalase activity (Scardovi et al., 1969).

Initially, the strains allotted to this species were isolated from the bovine rumen and did not ferment cellobiose, mannose, or xylose, and only rarely fermented arabinose (Scardovi et al., 1969). Pentose-fermenting strains subsequently isolated from piglets were recognized as *Bifidobacterium pseudolongum* subsp. *globosum* based on DNA relatedness data (Zani et al., 1974). Many other strains genetically assigned to *Bifidobacterium pseudolongum* subsp. *globosum* have been isolated from feces of various animals, including strains which ferment cellobiose, mannitol, or mannose, as well as some that slowly ferment or are inactive towards fructose (Scardovi et al., 1979a). Dextrin, galactose, glucose, glycogen, lactose, maltose, melibiose, raffinose, ribose, sucrose, and starch are all fermented, but not amygdalin, esculin, sodium gluconate, inositol, inulin, mannitol, mannose, melezitose, rhamnose, salicin, sorbitol, or trehalose. Fermentation of arabinose, fructose, and xylose give variable results (Scardovi et al., 1969). Methyl α-glucoside is either weakly or strongly fermented.

Folic acid, pantothenate, riboflavin, and thiamin are required for anaerobic growth. Ammonia satisfies nitrogen requirements. Growth in the presence of 4.5% sodium malate at 30°C is weakly positive or negative (Yaeshima et al., 1992b).

Unlike most species of the genus *Bifidobacterium*, the enzyme fructose-bisphosphate aldolase and hexose monophosphate dehydrogenases can be detected in cell-free extracts. Aldolase activity in intact cells was proven by the expected increase of acetate production from glucose degradation in the presence of iodoacetic acid (Scardovi and Trovatelli, 1969; Schramm et al., 1958). Glucose-6-phosphate dehydrogenase, undetectable in some strains, has been found to be either NAD^+ or $NADP^+$-dependent (Scardovi and Sgorbati, 1974).

Zymograms of 103 strains of *Bifidobacterium pseudolongum* subsp. *globosum* were shown to have transaldolase isozyme 2 and more than 80% of them contained 6PGD isozyme 6, four other 6PGD isozymes were found (Scardovi et al., 1979a; Table 21). However, Yaeshima et al. (1992b) found that the 6PGD mobilities of *Bifidobacterium pseudolongum* subsp. *globosum* strains RU 224^T, RU 230, and RU 256 were identical to those of *Bifidobacterium pseudolongum* subsp. *pseudolongum* PNC-2-9G^T.

PAGE protein patterns of selected strains isolated from various sources were identical and quite distinct from those of any other *Bifidobacterium* species (Biavati et al., 1982).

A study on the presence of bifidobacterial outer proteins (BIFOPs) in the cell-wall of 150 strains of *Bifidobacterium pseudolongum* subsp. *globosum* isolated from different animals was conducted by Mattarelli et al. (1993); 60% of the strains examined were apparently devoid of BIFOPs. BIFOP expression changes caused by growth temperature were observed in 70 strains of *Bifidobacterium pseudolongum* subsp. *globosum* isolated from different animals. In general, BIFOP expression at low temperature was considerably attenuated, whereas it increased at medium and high growth temperature (Mattarelli et al., 1999).

Large molecular mass plasmids (13.5, 24.5, and 46 MDa) were found in 22% of the *Bifidobacterium pseudolongum* subsp. *globosum* strains studied by Sgorbati et al. (1982).

Source: originally isolated from the bovine rumen (Scardovi et al., 1969) and later found in the feces of calves, chickens, lambs, piglets, rabbits, and rats, in a single specimen of feces from a human infant, and in sewage (Scardovi et al., 1979a). The type strain was isolated from a bovine rumen.

DNA G+C content (mol%): 64.1 ± 0.7 (T_m).

Type strain: RU 224, ATCC 25865, DSM 20092, JCM 5820, LMG 11569, NCIMB 702245.

Sequence accession nos (16S rRNA gene): M58736, D86194.

Additional comments: Rogosa (1974) considered this organism to be a synonym of *Bifidobacterium pseudolongum* Mitsuoka and, hence, the taxon was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980). Its revival as *Bifidobacterium globosum* was proposed by Biavati et al. (1982); Yaeshima et al. (1992b) reclassified *Bifidobacterium globosum as Bifidobacterium pseudolongum* subsp. g*lobosum*.

The DNA–DNA similarities found between the two subspecies reported by Scardovi et al. (1971b), Lauer and Kandler (1983), and Yaeshima et al. (1992b) are 69–73%, 76%, and 45–69%, respectively. Two intermediate groups, which showed 54–72% DNA relatedness with the two type strains, were reported by Yaeshima et al. (1992b). There is disagreement on the DNA similarity values to *Bifidobacterium cuniculi*: these have been reported to be 50–67% by Scardovi et al. (1979b) and 12% by Yaeshima et al. (1992b).

Members of the two subspecies and the two intermediate groups were divided into distinct subclusters basing on ribotyping analysis (Sakata et al., 2006). In addition, Masco et al. (2003) showed that the two subspecies could be divided into different intermediate groups using DNA fingerprinting, whereas HSP60 DNA sequence similarity between the two subspecies was 96%, a value corresponding to the interspecies level (Jian et al., 2001). Yaeshima et al. (1992b) found that the G+C content of the two subspecies was higher than 63 mol%, whereas Scardovi et al. (1971b) reported different values, such as 60.3 mol% for *Bifidobacterium pseudolongum* subsp. *pseudolongum* and 63.8 mol% for *Bifidobacterium pseudolongum* subsp. *globosum*.

Differences in plasmid content and in PAGE total cellular protein patterns have been demonstrated between the two subspecies (Biavati et al., 1982; Sgorbati et al., 1982), whereas the mobility of 6PGD of *Bifidobacterium pseudolongum* subsp. *pseudolongum* PNC-2-96^T against *Bifidobacterium pseudolongum* subsp. *globosum* Ru 224^T, Ru 230, and Ru 256 was found to be identical by Yaeshima et al. (1992b), but different by Scardovi et al. (1979a). However, the variability of 6PGD mobility observed among other strains of the two subspecies examined by Yaeshima et al. (1992b) was reported previously by Scardovi et al. (1979a). Considering all of these contrasting pieces of evidence, further studies are needed to clarify the taxonomic position of the two subspecies.

24. **Bifidobacterium psychraerophilum** Simpson, Ross, Fitzgerald and Stanton 2004, 404[VP]

psych.rae.ro′phi.lum. Gr. n. *psychros* cold; Gr. n. *aer aeros* air; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. neut. adj. *psychraerophilum* cold- and air-loving.

Short and irregularly shaped rods, approximately 0.7–1.0 μm wide and 0.8–1.5 μm long with occasional bifurcations, are arranged singly or in pairs (Figure 67, panel 24). Colonies on MRS agar under anaerobic conditions are white, circular and convex with smooth edges and reach a diameter of up to 3 mm after incubation for 3 d at 37°C. Colonies of ~1 mm are formed after 3 d incubation under aerobic conditions. A high tolerance is shown to oxygen. The organism grows on agar media under aerobic conditions, a trait that may be related to its cecal habitat. The optimal temperature for growth is 37°C and the maximum growth temperature is 42°C; growth does not occur at 46°C. Growth is evident at 4°C though reduced. The lowest pH recorded for growth is 4.0.

The highest similarity values for the partial HSP60 gene sequences, 83–58%, are shared with *Bifidobacterium asteroides*, *Bifidobacterium indicum*, and *Bifidobacterium minimum* (Simpson et al., 2004).

Source: the type strain was isolated from a pig cecum (contents and epithelium) in Fermoy, Ireland. The type strain has a PFGE type F profile (Simpson et al., 2004).

DNA G+C content (mol%): 59.2 (T_m).

Type strain: T16, LMG 21775, NCIMB 13940.

Sequence accession no. (16S rRNA gene): not available.

Additional comments: previously called "*Bifidobacterium pyschroaerophilum*" (Simpson et al., 2003).

25. **Bifidobacterium pullorum** Trovatelli, Crociani, Pedinotti and Scardovi 1974, 197[AL]

pul.lo′rum. L. n. *pullus* a chicken; L. pl. gen. n. *pullorum* of chickens.

Cells grown in TPY agar stabs are slightly curved, 2–8 μm long with tapered ends, and are mostly arranged in irregular chains which are often very long (Figure 67, panel 25). Cells are frequently poorly refractile and appear to be empty or vacuolized. Branching is rare. Anaerobic. CO_2 does not affect O_2 sensitivity or anaerobic growth. Lactic and acetic acids are produced in a ratio of 1:3.5 ± 0.2 in TPY medium but, unlike all other *Bifidobacterium* species, the isomeric type of lactic acid formed is DL. Requires *p*-aminobenzoic acid, folic acid, nicotinic acid, pyridoxine, thiamin, and Tween 80 for satisfactory growth.

Fructose-bisphosphate aldolase is present in cell-free extracts in considerable amounts (20–30 mU/mg protein). As with most *Bifidobacterium dentium* strains, neither 6PGD ($NADP^+$-or NAD^+-dependent) nor G6PDH can be detected.

Source: the type strain was isolated from chicken feces.

DNA G+C content (mol%): 67.4 ± 0.4 (T_m), the highest value found so far in the bifidobacteria.

Type strain: P145, ATCC 27685, DSM 20433, JCM 1214, LMG 21816.

Sequence accession no. (16S rRNA gene): D86196.

Additional comments: morphology is helpful in the recognition of this species. The taxon can be easily distinguished from the "animal" species of the genus, which also ferment arabinose, ribose, and xylose, because neither lactose nor starch is fermented (see Additional comments under *Bifidobacterium magnum*). It can be distinguished from other *Bifidobacterium* species by its fermentation characteristics (Table 22).

DNA relationships with *Bifidobacterium gallinarum* and *Bifidobacterium saeculare* are higher than with any other species of the genus *Bifidobacterium* (Biavati et al., 1991).

26. **Bifidobacterium ruminantium** Biavati and Mattarelli 1991, 165[VP]

ru.mi.nan′ti.um. L. part. adj. *ruminans, -antis* ruminating; N.L. gen. pl. n. *ruminantium* of ruminants.

Irregular rods (3.0–6.0 μm in length), rarely have terminal bifurcations, but often occur in pairs which form rare angles (Figure 67, panel 26). Surface colonies on TPY agar are soft, smooth, convex, circular with entire margins, cream to white, and glistening. Carbon dioxide has no effect on oxygen sensitivity, but it enhances anaerobic growth. The optimum temperature for growth is 38–42°C; growth does not occur below 25°C or above 45°C. The optimum initial pH for growth is 6.5–6.9; growth is delayed at pH 6.3 and 7.2, and does not occur at pH 4.5 or 8.

Dextrin, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannitol, melibiose, raffinose, D-ribose, sucrose, and starch are all fermented, but not L-arabinose, cellobiose, gluconate, glycerin, inulin, lactate, D-mannose, melezitose, L-rhamnose, D-sorbitol, trehalose, or D-xylose. Salicin fermentation, if it occurs, is slow.

Source: isolated from the bovine rumen, the source of the type strain.

DNA G+C content (mol%): 57 (T_m).

Type strain: Ru687, ATCC 49390, DSM 6489, JCM 8222, LMG 21811.

Sequence accession no. (16S rRNA gene): D86197.

Additional comments: Bifidobacterium ruminantium is more closely related to *Bifidobacterium adolescentis* than to any other *Bifidobacterium* species.

27. **Bifidobacterium saeculare** Biavati, Mattarelli and Crociani 1992b, 191[VP] (Effective publication: Biavati, Mattarelli and Crociani 1991, 391.)

sae.cu.la′re. L. neut. adj. *saeculare* of or belonging to a saeculum, centenary, commemorating the ninth centenary of the foundation of Bologna University.

Short, slightly curved rods, 2.0–4.0 μm long, occur in pairs. Longer, thicker, or spindle-shaped cells are common in some successive transfers. Branching cells are numerous at a low incubation temperature in liquid cultures (Figure 67, panel 27). Surface colonies on TPY agar are convex with entire edges, cream to white, glistening, and soft. Carbon dioxide does not affect oxygen sensitivity, but does enhance anaerobic growth. The optimal temperature for growth is 36–38°C; growth does not occur below 28°C or above 47°C. The initial optimal pH is 6.8–7.3; growth is delayed at pH 4.6 and 7.6, and does not occur at 5.5 or 8.9.

D-Glucosamine hydrochloride and xylan are fermented, but not alginate, amylopectin, amylose, arabinogalactan, bovine submaxillary mucin, chondroitin sulfate, α-D-fucose,

α-L-fucose, α-D-galacturonate, D-glucuronate, heparin, hyaluronate, laminarin, pectin, polygalacturonate, ovomucoid, or porcine gastric mucin. Penicillin-binding protein analysis has shown one detectable band with a mass of 52 kDa (Biavati et al., 1991).

Source: isolated from rabbit feces, the source of the type strain.

DNA G+C content (mol%): 63 (T_m).

Type strain: RA161, ATCC 49392, DSM 6531, JCM 8223, LMG 14934.

Sequence accession no. (16S rRNA gene): D89328.

Additional comments: the DNA relationships with *Bifidobacterium gallinarum* and *Bifidobacterium pullorum* are higher than with any other species of the genus *Bifidobacterium* (Biavati et al., 1991).

28. **Bifidobacterium scardovii** Hoyles, Inganäs, Falsen, Drancourt, Weiss, McCartney and Collins 2002, 998[VP]

scar.do′vi.i. N.L. gen. n. *scardovii* of Scardovi, named after Vittorio Scardovi, in recognition of his contribution to our knowledge of the bifidobacteria.

Rod-shaped cells, some of which are curved (Figure 67, panel 28). Colonies are 2–3 mm in diameter, convex, shiny, with a dense white center. Facultatively anaerobic and catalase-negative. Weak hemolysis is observed on Columbia blood agar.

Using API kits, acid is produced from L-arabinose, D-lactose, maltose, D-mannose, melibiose, raffinose, D-ribose, sucrose, and trehalose, but not from D-arabitol, cyclodextrin, glycogen, D-mannitol, methyl β-D-glucopyranoside, pullulan, D-sorbitol, or tagatose; acid may or may not be produced from melezitose.

Hippurate is not hydrolyzed. Positive for alanine phenylalanine proline arylamidase, arginine arylamidase, α-arabinosidase, α-fucosidase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, phenylalanine arylamidase, pyroglutamic acid arylamidase, serine arylamidase, and tyrosine arylamidase, but negative for alkaline phosphatase, arginine dihydrolase, β-galactosidase-6-phosphate, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, glycyl tryptophan arylamidase, proline arylamidase, and leucyl glycine arylamidase; a variable response is shown for alanine arylamidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, β-mannosidase, and urease.

Cell-wall murein is of the A3α type, L-Lys–L-Ser–L-Ala_2, a murein type that is unique amongst members of the genus *Bifidobacterium.*

Protein profiles clearly show that isolates of this species are not only separate from other closely related bifidobacteria, but represent a phenotypically homogeneous cluster displaying a very high intra-group similarity.

Source: isolated from human clinical sources. Habitat is not known. The type strain was isolated from human blood and another four strains were from human urine (three strains) and from the human hip (one strain).

DNA G+C content (mol%): 60±1 (HPLC).

Type strain: ATCC BAA-773, DSM 13734, CCUG 13008, JCM 12489, LMG 21589.

Sequence accession no. (16S rRNA gene): AJ307005.

29. **Bifidobacterium subtile** Biavati, Scardovi and Moore 1982, 369[VP]

sub′ti.le. L. neut. adj. *subtile* slender.

Cells grown in TPY agar stabs are slender, 0.5 × 2–3 µm, with rounded or tapered ends, and are sometimes curved. Branching is rare. Morphology (Figure 67, panel 29) is similar to that of *Bifidobacterium breve*, but cells of the latter are usually shorter and thicker, swollen and branched. Anaerobic. CO_2 does not affect O_2 sensitivity or anaerobic growth.

Optimal temperature for growth is 34–35.5°C, which is markedly lower than the range shown by other *Bifidobacterium* species (37–41°C). The sugar fermentation pattern is similar to that of *Bifidobacterium breve* but, unlike the latter, D-lactose is not fermented (Table 22). In addition, *Bifidobacterium subtile* ferments gluconate and starch, whereas *Bifidobacterium breve* does not.

Possesses high levels (10–15 mU/mg proteins in strain F395) of $NADP^+$/NAD^+-dependent G6PDH, but aldolase is not measurable. Transaldolase and 6PGD isozymes are among the most anodal amongst bifidobacteria (numbers 3 and 2, respectively); the 3-2 pattern occurs only in this species (Scardovi et al., 1979a). There are distinct PAGE protein patterns. Both human and animal types of F6PPK have been detected in cell-free extracts (Scardovi and Trovatelli, 1974).

Source: originally isolated in 1982 from specimens of wastewater and isolated very recently from caries lesions (Mantzourani et al., 2009); this was the first time that this species was found in a natural habitat. The type strain was isolated from wastewater.

DNA G+C content (mol%): 61.5 (T_m).

Type strain: F395, ATCC 27537, DSM 20096, LMG 11597.

Sequence accession no. (16S rRNA gene): D89378.

Additional comments: this taxon was previously described and referred to as the "*subtile*" DNA homology group and includes five strains isolated from sewage (Scardovi and Trovatelli, 1974).

30. **Bifidobacterium thermacidophilum** Dong, Xin, Jian, Liu and Ling 2000, 124[VP]

therm.ac.id.o′phil.um. Gr. n. *thermê* heat; N.L. n. *acidum* (from L. adj. *acidus* sour) acid; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. neut. adj. *thermacidophilum* heat/acid-loving.

Irregular rods, arranged singly or occasionally as "V" shapes (Figure 67, panels 30a and 30b); rods are 0.5 × 3–8 µm in size after 12–24 h in TPYG medium at 37°C. The fermentation products from glucose are acetic and lactic acids, in a molar ratio of 2.46–4.9:1. The optimal temperature for growth is 37–41°C and the temperature range for growth is 30–49.5°C. The optimal initial pH is 7.0–7.2; growth at pH 4.5 is quite good, but is delayed at pH 4.0.

D-Fructose, D-galactose, D-glucose, glycogen, maltose, melibiose, sucrose, raffinose, starch, and turanose are all fermented, but not mannitol, L-rhamnose, or sorbose. Fermentation of L-arabinose, gluconate, inulin, D-lactose, D-mannose, methyl α-D-glucoside, D-ribose, salicin, trehalose, and D-xylose is variable. Litmus milk is neither acidified nor coagulated by most strains.

Source: the type strain was isolated from an anaerobic digester treating wastewater from a bean-curd farm.

DNA G+C content (mol%): 56.9–61.0 (T_m).

Type strain: 36, AS 1.2282, DSM 15837, JCM 11165, LMG 21395.

Sequence accession no. (16S rRNA gene): AB016246.

Additional comments: deduced HSP60 protein sequences show 100% similarity among the thermophilic group that comprises *Bifidobacterium boum*, *Bifidobacterium thermacidophilum*, and *Bifidobacterium thermophilum*, although interspecies DNA homologies were 92.9–95.5%. Three signature amino acid residues at positions 156, 158, and 179 (Lys, Arg, and Ser) differentiate members of this group. The shared primary structures of HSP60 might relate to their thermophilic characteristics. High DNA reassociation values of 58.9% (Dong et al., 2000) and 82.2% (von Ah et al., 2007) are shown with *Bifidobacterium thermacidophilum* (see also *Bifidobacterium thermophilum*).

30a. **Bifidobacterium thermacidophilum subsp. thermacidophilum** (Dong, Xin, Jian, Liu and Ling 2000) Zhu, Li and Dong 2003, 1622[VP] (*Bifidobacterium thermacidophilum* Dong, Xin, Jian, Liu and Ling 2000, 124)

therm.ac.id.o′phil.um. Gr. n. *thermê* heat; N.L. n. *acidum* (from L. adj. *acidus* sour) acid; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. neut. adj. *thermacidophilum* heat/acid-loving.

All strains meet the species description. Colonies on TPY-glucose agar are circular, convex with entire edges, white, and reach 1.5–2 mm in diameter after 24 h cultivation. Anaerobic growth occurs in standing culture under 90% air plus 10% CO_2. Fermentation products from glucose are acetic and lactic acids at a molar ratio of 4.9:1. Liquid cultures of some strains can form a homogeneous sediment, which is readily dispersed by shaking. Maximum temperature for growth is 49.5°C. L-Arabinose, inulin, and D-mannose are fermented, but not trehalose. All strains grow well in media containing 2.0% (w/v) NaCl, but not 2.5% (w/v) NaCl.

Source: the type strain was isolated from the wastewater of a bean-curd farm in Beijing.

DNA G+C content (mol%): 56.85 ± 2.05 (T_m).

Type strain: 36, AS 1.2282, DSM 15837, JCM 11165, LMG 21395.

Sequence accession no. (16S rRNA gene): AB016246.

Additional comments: the DNA relationships with *Bifidobacterium thermophilum* are higher than with any other *Bifidobacterium* species.

30b. **Bifidobacterium thermacidophilum subsp. porcinum** Zhu, Li and Dong 2003, 1622[VP]

por.ci′num. L. neut. adj. *porcinum* of a hog.

All strains meet the species description. The fermentation products from glucose are acetic and lactic acids at a molar ratio of 2.46–2.72:1. Maximum temperature for growth is 46.5°C. Trehalose is fermented, but not L-arabinose, inulin, or D-mannose.

Source: isolated from piglet feces.

DNA G+C content (mol%): 61.02 ± 0.7 (T_m).

Type strain: P3-14, AS 1.3009, LMG 21689.

Sequence accession no. (16S rRNA gene): AY148470.

31. **Bifidobacterium thermophilum** Mitsuoka 1969, 59[AL]

ther.mo′phil.um. Gr. n. *thermê* heat; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. neut. adj. *thermophilum* heat-loving.

Cells grown in TPY agar stabs are long, slender, curved, and are arranged singly or in pairs, but never in clumps (Figure 67, panel 31). This morphology is shared by many other species of the genus *Bifidobacterium*.

Four biovars (a, b, c, and d) were distinguished by Mitsuoka (1969) based on differences in the fermentation of lactose and melezitose. Similar differences were found amongst strains isolated from bovine rumen, calf feces, and sewage (Scardovi et al., 1979b), and from piglet feces (Zani et al., 1974).

Bifidobacterium thermophilum, like *Bifidobacterium pseudolongum* subsp. *globosum*, can grow in 90% air plus 10% CO_2 without the cells becoming catalase- or pseudocatalase (hemin)-positive.

A few strains genetically assigned to *Bifidobacterium thermophilum* that ferment arabinose and xylose have been found in sewage and in piglets (Scardovi et al., 1979b).

Factors required for growth are pantothenate, pyridoxine, and riboflavin. Bases are not required and ammonia is the optimal nitrogen source.

Fructose-bisphosphate aldolase and hexose monophosphate dehydrogenases are always present in cell-free extracts (Scardovi et al., 1969); aldolase was spot-stained after electrophoresis (Scardovi and Sgorbati, 1974).

Source: isolated from bovine rumen, calf feces, sewage, and piglet feces. von Ah et al. (2007) reported the isolation of *Bifidobacterium thermophilum* from baby feces. The type strain was isolated from pig feces.

DNA G+C content (mol%): 60.0 (T_m).

Type strain: P2-91, ATCC 25525, DSM 20210, JCM 1207, LMG 11573, NCIMB 702253.

Sequence accession no. (16S rRNA gene): U10151.

Additional comments: Mitsuoka (1969) proposed the specific epithet *thermophilus* for strains of bifids which he isolated from the feces of chickens and swine, owing to their ability to grow at 46.5°C and their resistance to heating at 60°C for 30 min; Scardovi et al. (1969) named strains that fermented neither pentoses nor lactose, which he isolated from bovine rumens, as "*Bifidobacterium ruminale*". These strains did not ferment pentoses. Subsequent comparative data have shown that these species are identical (Biavati et al., 1982; Scardovi et al., 1971b, 1979a). See *Bifidobacterium choerinum* for details of how this organism and *Bifidobacterium boum* and *Bifidobacterium thermophilum* can be distinguished.

DNA relatedness values of 27–80% are shown to *Bifidobacterium boum. Bifidobacterium thermophilum* shows high DNA reassociation values of 58.9% (Dong et al., 2000) and 82.2% (von Ah et al., 2007) with *Bifidobacterium thermacidophilum*. The close DNA–DNA relationship between these two species reported by von Ah et al. (2007) questions the current classification of *Bifidobacterium thermacidophilum* as a discrete species. *Bifidobacterium thermophilum* and *Bifidobacterium thermacidophilum* share similar thermophilic characteristics.

The original spelling of the species was *Bifidobacterium thermophilium*, which was corrected by Hill et al. (1984) to *Bifidobacterium thermophilum*.

32. **Bifidobacterium tsurumiense** Okamoto, Benno, Leung and Maeda 2008, 146[VP]

tsu.ru.mi.en′se. N.L. neut. adj. *tsurumiense* pertaining to Tsurumi University, Yokohama, Japan.

Cells are short rods or coccoid-like when grown on *Brucella* HK blood agar under anaerobic conditions for 24 h (Figure 67, panel 32). Colonies on this medium are white, rough, and slightly convex. Growth occurs at 25 and 45°C; the optimal temperature for growth is 37°C. Facultatively anaerobic. F6PPK-positive; catalase- and oxidase-negative. End products of glucose fermentation are acetic and lactic acids at a molar ratio of 3:2.

Amygdalin, L-arabinose, arbutin, cellobiose, D-fructose, D-galactose, gentiobiose, gluconate, D-glucose, glycogen, 2-ketogluconate, 5-ketogluconate, D-lactose, maltose, D-mannitol, D-mannose, melibiose, methyl α-D-glucopyranoside, raffinose, D-ribose, salicin, starch, sucrose, trehalose, turanose, and D-xylose are fermented, but not *N*-acetylglucosamine, D-adonitol, D-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, L-fucose, glycerol, inositol, inulin, D-lyxose, melezitose, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, L-rhamnose, D-sorbitol, L-sorbose, D-tagatose, xylitol, or L-xylose. The cell-wall amino acids consist of Glu–Lys–Asp–$(Ala)_2$.

Source: isolated from dental plaque from hamsters fed with a high-carbohydrate diet.

DNA G+C content (mol%): 53.0 (T_m).

Type strain: OMB115, DSM 17777, JCM 13495

Sequence accession no. (16S rRNA gene): AB241106.

Genus II. **Aeriscardovia** Simpson, Ross, Fitzgerald and Stanton 2004, 405[VP]

Paola Mattarelli and Bruno Biavati

Aer.i.scar.do′vi.a. L. masc. n. *aer, aeris* air; N.L. fem. n. *Scardovia* a bacterial generic name to honor Vittorio Scardovi, an Italian microbiologist; N.L. fem. n. *Aeriscardovia* cells similar to those of the genus *Scardovia* that can grow in air.

Gram-stain-positive, catalase- and oxidase-negative, nonmotile, non-spore-forming actinomycete that forms short and irregularly shaped rods. Optimal growth occurs under anaerobic conditions, with aerobic growth yielding elongated cells. Isolated from a porcine cecum. 16S rRNA and HSP60 gene sequence comparisons indicate that *Aeriscardovia* belongs to the family *Bifidobacteriaceae*. Only the type species, *Aeriscardovia aeriphila*, has been described.

DNA G+C content (mol%): 54.7 (HPLC).

Type species: **Aeriscardovia aeriphila** Simpson, Ross, Fitzgerald and Stanton 2004, 405[VP].

Further descriptive information

Phylogeny. In a study of 160 bifidobacterial strains isolated from either the lumen or the epithelium of a porcine cecum, two groups were highlighted, one containing 83 isolates (group I) and the other containing 77 isolates (group II) (Simpson et al., 2003). Group 1 showed a PFGE F profile and group II showed PFGE profiles B, E, and Ea. Based primarily on 16S rRNA gene sequencing, groups I and II were considered to represent novel species, namely "*Bifidobacterium pyschroaerophilum*" and "*Bifidobacterium aerophilum*", respectively. DNA G+C content and partial heat-shock protein 60 (HSP60) gene sequence analysis confirmed the proposal for "*Bifidobacterium pyschroaerophilum*", corrected to *Bifidobacterium pyschraerophilum* (Simpson et al., 2004). The DNA G+C content of "*Bifidobacterium aerophilum*" was relatively low and consistent with its assignment to a subcluster comprising *Alloscardovia*, *Metascardovia*, *Parascardovia*, and *Scardovia* of the 16S rRNA gene sequence-based phylogenetic tree (Figure 66). However, partial HSP60 gene sequencing showed that "*Bifidobacterium aerophilum*" could be distinguished from members of the genera *Bifidobacterium*, *Parascardovia*, and *Scardovia*, sharing similarity values with these taxa of 73.8%, 72.0%, and 71.4%, respectively; the former value is comparable to those reported for *Parascardovia denticolens* and *Scardovia inopinata* (Jian et al., 2001). Consequently, "*Bifidobacterium aerophilum*" was reclassified as *Aeriscardovia aeriphila* gen. nov., sp. nov. (Simpson et al., 2004).

Anaerobiosis. *Aeriscardovia* strains show a high tolerance to oxygen and grow on agar media under aerobic conditions, a trait that may relate to their cecal habitat. Under aerobic growth conditions, the short-rod morphology of *Aeriscardovia aeriphila* is lengthened considerably, possibly due to incomplete cell division.

Maintenance procedures

Aeriscardovia aeriphila can be maintained at −135°C or as freeze-dried cultures by using standard procedures described for the genus *Bifidobacterium*.

List of species of the genus *Aeriscardovia*

1. **Aeriscardovia aeriphila** Simpson, Ross, Fitzgerald and Stanton 2004, 405[VP]

ae.ri′phi.la. L. masc. n. *aer, aeris* air; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *aeriphila* air-loving.

Short, irregularly shaped rods, approximately 0.6–0.9 µm wide and 0.8–1.5 µm long, are arranged singly or in pairs, but not in chains (Figure 70). Colonies on modified de Man–Rogosa–Sharpe (mMRS) medium supplemented with 0.05% (w/v) cysteine/HCl under anaerobic conditions are gray–white, circular, and flat to convex with entire edges and reach a diameter of up to 3 mm after 3 d incubation at 37°C. Colonies are formed under aerobic conditions, but a diameter of only ~1 mm is attained after 5 d incubation. Under aerobic conditions, cell morphology includes elongated cells that are approximately 4–6 mm in length.

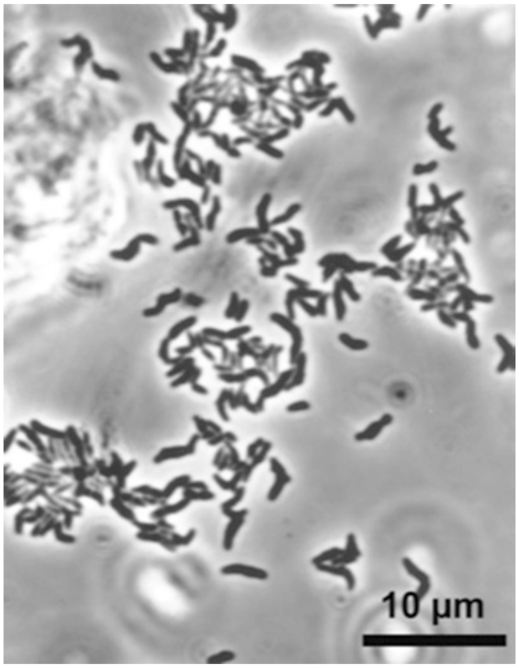

FIGURE 70. Cellular morphology of *Aeriscardovia aeriphila* T6^T grown in liquid TPY medium. Phase-contrast photomicrograph (magnification 1500×).

A high tolerance to oxygen is shown. This species grows under aerobic conditions on agar media, as does *Alloscardovia omnicolens*, *Bifidobacterium psychraerophilum*, *Bifidobacterium scardovii*, *Bifidobacterium tsurumiense*, *Gardnerella vaginalis*, and *Metascardovia criceti*. The optimal growth temperature is 37°C, with a maximum of 46°C and a minimum of 30°C; growth does not occur at 25 or 48°C. In mMRS medium, the lowest pH value recorded for growth is 4.2 and the minimum initial pH for growth is 4.5.

Acid is formed from arabinose, maltose, mannose, raffinose, salicin, sucrose, and xylose, but not from cellobiose, lactose, mannitol, melezitose, sorbitol, or trehalose. L-Arabinose, D-glucose, maltose, D-mannose, raffinose, and salicin are fermented, but not cellobiose, glycerol, D-lactose, D-mannitol, L-rhamnose, D-sorbitol, or trehalose. Fermentation of melezitose, sucrose, and D-xylose is variable.

Positive for α-arabinosidase, arginine arylamidase, glycine arylamidase, α- and β-galactosidases, α- and β-glucosidases, histidine arylamidase, leucine arylamidase, phenylalanine arylamidase, proline arylamidase, tyrosine arylamidase, and serine arylamidase; negative for *N*-acetyl-β-glucosaminidase, alanine arylamidase, alkaline phosphatase, β-galactosidase-6-phosphate, β-glucuronidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, leucyl glycine arylamidase, pyroglutamic acid arylamidase, and urease. Does not liquefy gelatin, produce indole, or reduce nitrate to nitrite.

A single plasmid (30 kbp) may be present in strain T8 and other isolates with the same PFGE type Ea based on macrorestriction pattern data.

Source: isolated from a pig cecum (contents and epithelium) in Fermoy, Ireland.

DNA G+C content (mol%): 54.7 (HPLC).

Type strain: T6, LMG 21773, NCIMB 13939.

Sequence accession no. (16S rRNA gene): AY174107.

Additional comments: from PFGE analysis, the 77 pig cecal isolates belonging to *Aeriscardovia* appeared to represent three strains, termed PFGE types B, E, and Ea. Previously known as "*Bifidobacterium aerophilum*".

Genus III. **Alloscardovia** Huys, Vancanneyt, D'Haene, Falsen, Wauters and Vandamme 2007, 1445^{VP}

Paola Mattarelli and Bruno Biavati

Al.lo.scar.do′vi.a. Gr. adj. *allos* different; N.L. fem. n. *Scardovia* a bacterial generic name; N.L. fem. n. *Alloscardovia* an organism related to, but different from, *Scardovia* and related genera.

Gram-stain-positive, catalase- and oxidase-negative, nonmotile, non-spore-forming actinomycete that forms short irregularly shaped rods. **Optimal growth occurs under anaerobic conditions on modified Columbia agar (MCA) or modified de Man–Rogosa–Sharpe medium (mMRS) after 24 h at 37°C, but slow aerobic growth (72 h), producing pinpoint-sized colonies, is also observed on MCA**. Isolated from various human clinical samples, but data are not currently available on potential pathogenic relevance or virulence factors. On the basis of 16S rRNA and HSP60 gene sequence analyses, *Alloscardovia* represents a new genus of the family *Bifidobacteriaceae*. Only one species has been described, *Alloscardovia omnicolens*.

DNA G+C content (mol%): 47.8 ± 0.5 (T_m).

Type species: **Alloscardovia omnicolens** Huys, Vancanneyt, D'Haene, Falsen, Wauters and Vandamme 2007, 1445^{VP}.

Further descriptive information

16S rRNA gene sequence data show that *Alloscardovia omnicolens* is most closely related to *Scardovia inopinata* (92.9–93.1%) and *Parascardovia denticolens* (93.0–93.2%). Its sequence similarities to *Aeriscardovia aeriphila*, *Gardnerella vaginalis*, and *Bifidobacterium* species range from 89.8 to 91.8%. Partial *hsp60* gene sequence data clearly separate *Alloscardovia* from its closest phylogenetic neighbors, namely *Parascardovia denticolens* (74.6–77.3% sequence similarity), *Scardovia inopinata* (75.0–77.7%), and *Gardnerella vaginalis* (80.3–81.5%). 16S rRNA and *hsp60* gene sequence analyses indicate that *Alloscardovia* forms a distinct branch within the family *Bifidobacteriaceae* and is sufficiently divergent from the other members of this family to be proposed as a new genus (Huys et al., 2007). A 16S rRNA phylogenetic tree of the family *Bifidobacteriaceae* is shown in Figure 66.

The DNA G+C contents of *Alloscardovia omnicolens* strains (47.3–48.3 mol%) are consistent with their phylogenetic positioning in the family *Bifidobacteriaceae* with *Gardnerella vaginalis* (41.8–43.0 mol%), *Metascardovia criceti* (53 mol%), *Parascardovia denticolens* (55 mol%), and *Scardovia inopinata* (45 mol%) as the closest relatives.

Maintenance procedures

Alloscardovia omnicolens can be maintained at −135°C or as freeze-dried cultures by using standard procedures described for the genus *Bifidobacterium*.

List of species of the genus *Alloscardovia*

1. **Alloscardovia omnicolens** Huys, Vancanneyt, D'Haene, Falsen, Wauters and Vandamme 2007, 1445^VP^

om.ni.co′lens. L. adj. *omnis* every; L. v. *colere* to dwell; L. part. adj. *colens* dwelling; N.L. part. adj. *omnicolens* dwelling everywhere in the human body.

Short irregularly shaped rods arranged singly or in pairs (Figure 71). Optimal growth occurs under anaerobic conditions on modified Columbia agar (MCA) and on modified MRS (mMRS) after 24 h at 37°C, but slow aerobic growth (72 h), resulting in pinpoint-sized colonies, is observed on MCA. Anaerobic growth on MCA occurs at 28°C (after 72 h), 37–40°C (after 24 h), and 45°C (after 96 h), but not at 50°C (after 96 h).

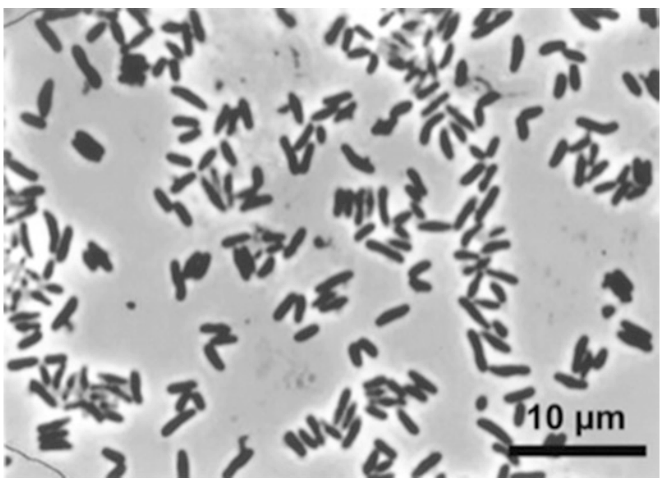

FIGURE 71. Cellular morphology of *Alloscardovia omnicolens* CCUG 31649^T^ grown in liquid TPY medium. Phase-contrast photomicrograph (magnification 1500×).

L-Arabinose, D-glucose, maltose, raffinose, salicin, sucrose, and D-xylose are fermented, but not glycerol (except for strain CCUG 31736), mannitol (except for strains CCUG 27412 and CCUG 31736), rhamnose (except for strain CCUG 31736), or sorbitol (except for strains CCUG 27412 and CCUG 31736).

Produces α-arabinosidase (except for strain CCUG 44766), arginine arylamidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, phenylalanine arylamidase, proline arylamidase, serine arylamidase, tyrosine arylamidase, α-galactosidase, β-galactosidase, α-glucosidase, and β-glucosidase, but not alanine arylamidase, glutamyl glutamic acid arylamidase, leucyl glycine arylamidase, pyroglutamic acid arylamidase, glutamic acid decarboxylase, arginine dihydrolase, α-fucosidase, β-galactosidase 6-phosphate, *N*-acetyl-β-glucosaminidase, β-glucuronidase, alkaline phosphatase, or urease.

Esculin is hydrolyzed. Nitrate is not reduced to nitrite. Gelatin is not liquefied nor is indole produced. Little, if any, β-hemolysis is observed on blood-supplemented MCA.

Source: isolated from various human clinical samples, including blood and urine and from the urethra, oral cavity, tonsils, abscesses of lungs, and aortic valves. The type strain was isolated from the tonsils of a 25-year-old woman from Kristianstad, Sweden, in 1993.

DNA G+C content (mol%): 47.8 ± 0.5 (T_m).

Type strain: CCUG 31649, LMG 23792.

Sequence accession no. (16S rRNA gene): AM419460.

Additional comments: strains CCUG 7132, CCUG 50589, and CCUG 26938 have been deposited in the BCCM/LMG Bacteria Collection as LMG 23793–23795, respectively.

Genus IV. **Gardnerella** Greenwood and Pickett 1980, 176^VP^

VIRGINIE STORMS AND PETER VANDAMME

Gard.ner.el′la. N.L. fem. dim. n. *Gardnerella* named after H.L. Gardner.

Pleomorphic rods ~0.5 μm in diameter and 1.5–2.5 μm in length. Filaments do not occur. Neither capsules nor endospores are formed. **Gram-stain-negative to Gram-stain-variable. Nonmotile.** Facultatively anaerobic. Fastidious in growth requirements. **Catalase- and oxidase-negative.** Chemo-organotrophic, with a fermentative type of metabolism. **Acid, but no gas, is produced** from a variety of carbohydrates, including **maltose and starch.** Acetic acid is the major product of fermentation. **Hippurate is hydrolyzed. Human blood, but not sheep blood, is hemolyzed.** Found in the human genital and urinary tracts.

DNA G+C content (mol%): 42–44 (Bd).

Type species: **Gardnerella vaginalis** (Gardner and Dukes 1955) Greenwood and Pickett 1980, 176^VP^ (*Haemophilus vaginalis* Gardner and Dukes 1955, 963).

Further descriptive information

Cell morphology. Cells appear as small pleomorphic bacilli and coccobacilli which may stain Gram-stain-negative or Gram-stain-variable (Zinnemann and Turner, 1963). They do not give an acid-fast reaction. Sudanophilic inclusions and metachromatic granules occur in the cells.

Cell-wall composition. The cell walls contain the amino acids *N*-acetylglucosamine, alanine, aspartic acid, glutamic acid, glycine, histidine, lysine, methionine, proline, serine, threonine, and tryptophan, but diaminopimelic and teichoic acids have not been detected (Criswell et al., 1971). The presence of alanine, glycine, glutamic acid, and lysine was confirmed by O'Donnell et al. (1984). Cellular fatty acid profiles consist of straight-chain saturated and unsaturated non-hydroxylated fatty acids with hexadecanoic acid (16:0) and octadecenoic acid (18:1) as major components (Greenwood and Pickett, 1980; Moss and Dunkelberg, 1969; O'Donnell et al., 1984; Van Esbroeck et al., 1996). Other cellular fatty acid components include tetradecanoic acid (14:0), hexadecanoic acid (16:1 ω7*c*), octadecadenoic acid (18:2 ω6,9*c*), and octadecanoic acid (18:0).

Carbohydrate analysis has indicated 6-deoxytalose and no arabinose in the cell walls of the type strain (Vickerstaff and Cole, 1969). *Gardnerella vaginalis* strains contain very characteristic polar lipid patterns consisting of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, five partially identified glycolipids, and an uncharacterized phospholipid (O'Donnell et al., 1984).

Fine structure. Electron microscopy of cell walls has presented conflicting results. Reyn et al. (1966) reported a microscopic morphology, particularly of the cell walls and septa, closely resembling that of a Gram-stain-positive organism. On the other hand, Criswell et al. (1971, 1972) reported that the fine structure of walls was more typical of a Gram-stain-negative organism. A re-examination of the cell-wall ultrastructure of the *Gardnerella vaginalis* type strain and of clinical isolates demonstrated that the cell walls of these bacteria have a Gram-stain-positive type of organization and that the unusual thinness of the cell walls accounts for the Gram-stain-negative staining tendency observed regularly (Sadhu et al., 1989).

Nutrition and growth conditions. Although most strains of *Gardnerella* are facultatively anaerobic, obligately anaerobic strains have been described.

Slight, if any, growth occurs on nutrient agar (Piot et al., 1980). Growth does not occur on most common selective media including tellurite (0.01%) agar, sodium chloride (3%) agar, bile (1%) agar, Rogosa agar, or Thayer–Martin agar. On Vaginalis agar* colonies are pinpoint after incubation for 24 h and are 0.4–0.5 mm in diameter after 48 h. The colonies are round, opaque, and smooth. They become larger than 0.5 mm after incubation beyond 48 h, but their viability decreases rapidly.

*Vaginalis agar consists of Columbia agar base (BBL) containing 1% proteose peptone no. 3 (Difco). After the medium has been autoclaved and cooled to 45–50°C, human blood (5%, v/v) preserved with citrate, phosphate, and glucose is added aseptically to the medium.

Colonial and cultural characteristics. Colonies are nonhemolytic on sheep blood agar, but the majority of strains exhibit diffuse β-hemolysis on human or rabbit blood. Little or no hemolysis is observed on horse blood.

The optimum growth temperature is 35–37°C. Growth may also occur at 25 and 42°C. The optimum pH range is 6.0–6.5. Slight growth occurs at pH 4.5, but not at pH 4.0 (Greenwood and Pickett, 1979). Obligately anaerobic strains have been described (Malone et al., 1975).

Gardnerella strains are fastidious in their nutritional requirements, but do not need nicotinamide adenine dinucleotide (V factor), hemin (X factor), or coenzyme-like substances (Dunkelberg and McVeigh, 1969; Edmunds, 1962). They have been reported to require biotin, folic acid, niacin, thiamine, riboflavin, and two or more purines/pyrimidines (Dunkelberg and McVeigh, 1969). Growth is improved with fermentable carbohydrates and certain peptones.

Metabolism and metabolic pathways. The major product of sugar fermentation is acetic acid (Moss and Dunkelberg, 1969), but some strains also produce one or more of lactic, formic, or succinic acids (Malone et al., 1975). Gas is not formed from sugar fermentation. Acid is produced from dextrin, glucose, maltose, ribose, and starch, but not from D-arabitol, arbutin, cellobiose, glycerol, methyl β-D-glucopyranoside, inositol, lactose, mannitol, melezitose, melibiose, raffinose, rhamnose, salicin, sucrose, tagatose, trehalose, or xylose. Production of acid from L-arabinose, fructose, galactose, inulin, and mannose is strain dependent.

Starch is hydrolyzed, but not esculin, gelatin, tributyrin, or urea. Voges–Proskauer test is negative; methyl red test is positive. Does not produce indole, H_2S, or acetoin, show phenylalanine deaminase activity, or degrade Tween 80. Does not produce nitrite from nitrate, or have arginine and ornithine decarboxylase or lysine dihydrolase activities. Gluconate is oxidized to 2-ketogluconate. Hydrolysis of *O*-nitrophenyl-β-D-galactopyranoside and casein, and lipase activity are strain dependent.

Positive for β-D-galactosidase, *N*-acetyl-α-D-glucosaminidase, α-D-glucosidase, α-maltosidase, F6PPK, and pyrazinamidase activities and also for the following arylamidases: L-alanine, alanyl-phenylalanyl-proline, β-alanine, L-arginine, *S*-benzyl-cysteine, α-L-glutamate, α-L-glutamyl-L-histidine, glycine, glycyl-L-arginine, glycyl-proline, L-histidine, L-histidyl-L-leucyl-L-histidine, L-histidyl-L-serine, L-hydroxyproline, L-leucyl-L-alanine, leucyl-glycine, L-lysine, L-lysyl-L-lysine, L-lysyl-L-serine-4-methoxy, methionine, L-ornithine, L-phenylalanine, L-phenylalanyl-L-arginine, L-phenylalanyl-L-prolyl-L-alanine, L-proline, L-prolyl-L-arginine, L-pyrrolidone, L-serine, L-seryl-tyrosine, L-threonine, and L-tyrosine.

Negative for α-L-arabinosidase, esterase (C_6, C_{16}, and C_{18}), α-L-fucosidase, β-D-fucosidase, β-L-fucosidase, α-D-galactosidase, phospho-β-D-galactosidase, β-D-galacturonohydrolase, *N*-acetyl-β-D-glucosaminidase, β-D-glucosidase, β-D-glucuronidase, γ-glutamyltransferase, β-D-lactosidase, β-maltosidase, β-D-mannosidase, α-D-xylosidase, and β-D-xylosidase activities and for the following arylamidases: *N*-acetyl-glycyl-L-lysine, α-aspartyl-L-arginine, *N*-benzoyl-L-alanine-4-methoxy, *N*-carboxybenzoxy-glycyl-L-arginine, *N*-carboxybenzoxy-glycyl-glycyl-arginine, α-L-glutamyl-α-L-glutamine, glycyl-tryptophan, and pyroglutamic acid.

Antibiotic or drug sensitivity. All strains are susceptible to ampicillin, carbenicillin, oxacillin, penicillin, and vancomycin, and all are uniformly resistant to colistin, nalidixic acid, neomycin, and sulfadiazine at the usual therapeutic levels. Strains differ in susceptibility to kanamycin, tetracycline, gentamicin, and tobramycin (Greenwood and Pickett, 1980; McCarthy et al., 1979). Metronidazole is effective *in vivo*, but gives variable results in *in vitro* susceptibility tests (Balsdon et al., 1980).

Pathogenicity. *Gardnerella vaginalis* has been considered to be the cause of bacterial nonspecific vaginitis or bacterial vaginosis. It has also occasionally been reported to cause bacteremia in postpartum women and in patients following septic abortion and transurethral resection of the prostate. *Gardnerella vaginalis* has been isolated from reproductive tracts of mares (Salmon et al., 1991). Nowadays, bacterial vaginosis is known to be associated with a diverse spectrum of mostly anaerobic bacteria, including species of the genera *Anaerococcus*, *Atopobium*, *Bacteroides*, *Finegoldia*, *Gemella*, *Mobiluncus*, and *Prevotella* (Bradshaw et al., 2006; Fredricks et al., 2005). In addition, recent studies (Fredricks et al., 2007) demonstrated that *Gardnerella vaginalis* is an unreliable indicator of bacterial vaginosis, as demonstrated by the high rate of detection in subjects without bacterial vaginosis.

Ecology. *Gardnerella vaginalis* has been isolated from the anorectal flora of healthy adults of both sexes as well as from that of children. It is part of the endogenous flora in women of reproductive age. The organism can be recovered from the urethras of male partners of women with bacterial vaginosis and, more rarely, from blood samples. It can also cause infections in newborns and appears to have worldwide distribution.

Isolation and detection procedures

Most commercial blood culture broths used for the isolation of fastidious bacteria contain sodium polyetholsulfonate as an anticoagulant which inhibits the growth of *Gardnerella*. Isolation of *Gardnerella vaginalis* from genital samples can be accomplished by adding gelatin to such media or by using selective media, namely human blood bilayer Tween agar or Vaginalis agar. One quadrant is inoculated with the swab and the plate is streaked for isolation of colonies. Inoculated plates are incubated for 48 h at 35°C in either a candle extinction jar lined with water-saturated absorbent paper or in a CO_2 incubator. *Gardnerella vaginalis* forms opaque, domed, entire colonies, ~0.5 mm in diameter, that are surrounded by a small zone of diffuse β-hemolysis. *Gardnerella vaginalis* colonies appear as pinpoint and nonhemolytic on 5% sheep blood agar. *Gardnerella* cells appear as small pleomorphic Gram-stain-negative or Gram-stain-variable coccobacilli and short rods upon Gram stain.

Another isolation medium is peptone-starch-glucose medium* (Dunkelberg et al., 1970). This medium is inoculated and incubated as outlined above for Vaginalis agar. On this medium, colonies of *Gardnerella vaginalis* are 0.5–2.0 mm in diameter, dull white, convex, domed, somewhat conical in shape, and entire.

Detection of *Gardnerella vaginalis* in vaginal specimens by means of a DNA-probe-based system, Affirm VPIII (Becton Dickinson), has been reported to be useful as a surrogate for wet mount cell examination (Briselden and Hillier, 1994). Several PCR tests that allow a more sensitive detection and identification of *Gardnerella vaginalis* have been described, but the specificity of these assays is not always optimal (Fredricks et al., 2007; Nath et al., 2000; Obata-Yasuoka et al., 2002; van Belkum et al., 1995; Zariffard et al., 2002).

Maintenance procedures

Working stock cultures should be transferred every 48 h to ensure viability. This requirement for frequent transfer appears to be independent of the type of maintenance medium or temperature of storage. Stock strains may be preserved indefinitely by lyophilization in either rabbit serum or 10% skim milk.

Differentiation of the genus *Gardnerella* from other genera

Several commercial systems for the identification of fastidious Gram-stain-negative bacteria can be used adequately to identify *Gardnerella vaginalis*. However, typical appearance on Gram stain, β-hemolytic behavior on human blood bilayer Tween agar or Vaginalis agar, the lack of hemolysis on 5% sheep blood agar, the absence of catalase and oxidase activities, and the presence of hippurate hydrolysis allow presumptive identification.

Gardnerella vaginalis-like organisms recovered from patients with bacterial vaginosis have been demonstrated to represent *Actinomyces turicensis* strains (Van Esbroeck et al., 1996; Vandamme et al., 1998). *Gardnerella vaginalis* can be differentiated from these organisms as it has acetic acid as the main end product of glucose fermentation and is unable to produce acid from xylose, whereas *Actinomyces turicensis* strains have succinic acid as the end product and produce acid from xylose.

Taxonomic comments

Before the study of bacterial phylogeny through sequence analysis of conserved chronometers like rRNA genes, the generic assignment of this organism was the subject of debate. It has been classified as a member of the genera *Corynebacterium* and *Haemophilus* and its assignment to many other Gram-stain-positive and Gram-stain-negative genera has been discussed (Greenwood and Pickett, 1980; Lapage, 1974; Piot et al., 1980). Nevertheless, its unique cell-wall structure and biochemical characteristics led Greenwood and Pickett (1980) and Piot et al. (1980) to conclude that this organism was best classified in a distinct genus, *Gardnerella*. Analysis of the 16S rRNA gene sequence of the *Gardnerella vaginalis* type strain (Van Esbroeck et al., 1996) confirmed its unique phylogenetic position among the *Actinobacteria* with members of the genus *Bifidobacterium* as its closest phylogenetic neighbors (Figure 72). A phylogenetic analysis based on *hsp60* gene sequences revealed the same taxonomic neighborhood (Huys et al., 2007).

*Peptone-starch-glucose agar contains (g/l): proteose peptone no. 3 (Difco), 20.0; soluble starch, 10.0; glucose, 2.0; Na_2HPO_4, 1.0; $NaH_2PO_4 \cdot H_2O$, 1.0; agar, 15.0. A more recent formulation of this medium omits the phosphate buffer.

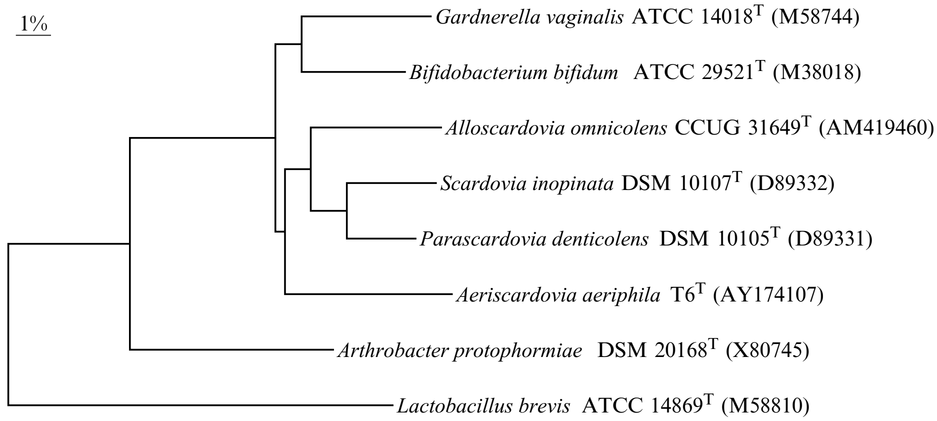

FIGURE 72. Neighbor-joining phylogenetic tree derived from analysis of nearly complete 16S rRNA gene sequences of the type strains of *Gardnerella vaginalis*, the type species of its closest phylogenetic neighbors, and of *Arthrobacter protophormiae* and *Lactobacillus brevis* as outgroups. Bar = 1% difference in 16S rRNA nucleotide sequences.

Sequence accession no. (16S rRNA gene): M58744.

Genus V. **Metascardovia** Okamoto, Benno, Leung and Maeda 2007b, 2449[VP] (Effective publication: Okamoto, Benno, Leung and Maeda 2007a, 752.)

Paola Mattarelli and Bruno Biavati

Me.ta.scar.do′vi.a. Gr. adv. *meta* besides; N.L. fem. n. *Scardovia* a bacterial genus name; N.L. fem. n. *Metascardovia* a genus besides *Scardovia*.

Gram-stain-positive, facultatively anaerobic actinomycete that produces short and irregular shaped rods. F6PPK-positive; catalase- and oxidase-negative. Growth occurs at 25°C and 45°C (optimal at 37°C). Able to grow on cadmium fluoride acriflavin tellurite (CFAT) and *Lactobacillus* selection (LBS) agars (Okamoto et al., 2007a). Fermentation products from glucose are acetic and L-(+)-lactic acids in the molar ratio 3:2. 16S rRNA and HSP60 gene sequence data place *Metascardovia* in the family *Bifidobacteriaceae*. One species, *Metascardovia criceti*, has been described.

DNA G+C content (mol%): 53 (T_m).

Type species: **Metascardovia criceti** Okamoto, Benno, Leung and Maeda 2007b, 2449[VP] (Effective publication: Okamoto, Benno, Leung and Maeda 2007a, 752.).

Further descriptive information

Phylogeny. A phylogenetic tree based on 36 partial 16S rRNA gene sequences, including those from members of the genus *Bifidobacterium* and related genera, and rooted using *Escherichia coli* K-12, showed that *Metascardovia* was sharply separated from a cluster of *Bifidobacterium* species and was most closely related to

Aeriscardovia aeriphila, *Parascardovia denticolens*, and S*cardovia inopinata* (Okamoto et al., 2007a) (Figure 66). The 16S rRNA gene sequence similarity values of *Metascardovia criceti* OMB105^T with the type strains of *Parascardovia denticolens*, *Scardovia inopinata*, and *Aeriscardovia aeriphila* were 91.7%, 91.1%, and 90.0%, respectively. A phylogenetic tree based on 35 HSP60 gene sequences, including those from members of the genus *Bifidobacterium* and related genera, using 528 bp (corresponding to positions within the 304–831 nt region of *Escherichia coli* K-12 HSP60 gene) showed that *Metascardovia criceti* was well separated from a cluster of *Bifidobacterium* species, and was most closely related to *Gardnerella vaginalis* and *Scardovia inopinata*. It shared partial HSP60 gene similarities with *Parascardovia denticolens*, *Scardovia inopinata*, and *Gardnerella vaginalis* of 76.2%, 75.6%, and 74.8%, respectively.

Anaerobiosis. *Metascardovia* strains grow under aerobic conditions, as do other members of the family *Bifidobacteriaceae*, such as *Aeriscardovia aeriphila*, *Bifidobacterium psychraerophilum*, *Bifidobacterium scardovii*, and *Gardnerella vaginalis* (Hoyles et al., 2002; Simpson et al., 2004; Van Esbroeck et al., 1996). It would be of interest to understand the mechanism by which some *Bifidobacteriaceae* species are able to grow under aerobic conditions.

Maintenance procedures

Metascardovia criceti can be maintained at −135°C or as freeze-dried cultures by using standard procedures described for the genus *Bifidobacterium*.

List of species of the genus *Metascardovia*

1. **Metascardovia criceti** Okamoto, Benno, Leung and Maeda 2007b, 2449^{VP} (Effective publication: Okamoto, Benno, Leung and Maeda 2007a, 752.)

cri.ce′ti. N.L. gen. n. *criceti* of hamster.

Brownish-gray, rough, slightly convex colonies are formed on *Brucella* HK blood agar. When grown on media under anaerobic conditions for 24 h, irregular rods, with occasional bifurcated extremities and tapered ends, are formed (Figure 73). Longer incubation under similar conditions leads to changes in the Gram reaction and the formation of shorter rods.

Amygdalin, L-arabinose, arbutin, cellobiose, fructose, galactose, gentiobiose, 2-ketogluconate, glucose, maltose, mannose, melezitose, melibiose, raffinose, ribose, salicin, sucrose, trehalose, turanose, D-xylose, and lactose are fermented, but not adonitol, D-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, L-fucose, gluconate, 5-ketogluconate, methyl α-D-glucopyranoside, *N*-acetylglucosamine, glycerol, glycogen, inositol, inulin, D-lyxose, mannitol, methyl α-D-mannopyranoside, rhamnose sorbitol, sorbose, starch, D-tagatose, xylitol, methyl β-D-xylopyranoside, or L-xylose.

α-Arabinosidase, alanine arylamidase, arginine arylamidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, phenylalanine arylamidase, proline arylamidase, serine arylamidase, tyrosine arylamidase, esterase, α-galactosidase, lipase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, acid phosphatase, and α-phosphoamidase are formed, but not cysteine arylamidase, glutamyl glutamic acid arylamidase, leucyl glycine arylamidase, pyroglutamine arylamidase, valine arylamidase, arginine dihydrolase, catalase, glutamic acid decarboxylase, α-fucosidase, β-galactosidase-6-phosphate, *N*-acetyl-β-glucosaminidase, β-glucuronidase, lipase, α-mannosidase, alkaline phosphatase, trypsin, chymotrypsin, or urease.

Metascardovia criceti, like *Bifidobacterium dentium*, grows on selective media such as LBS (Becton Dickinson) and CFAT agars, unlike *Parascardovia denticolens*, *Scardovia inopinata*, and other members of the family *Bifidobacteriaceae* (Okamoto et al., 2007a). Does not hydrolyze esculin or gelatin, or produce indole. Nitrate is not produced.

The cell-wall type is Glu–Lys–Ser–(Ala)$_2$.

Source: isolated from dental plaque of hamsters fed with a high-carbohydrate diet.

DNA G+C content (mol%): 53 (T_m).

Type strain: OMB105, JCM 13493, DSM 17774.

Sequence accession no. (16S rRNA gene): AB241105.

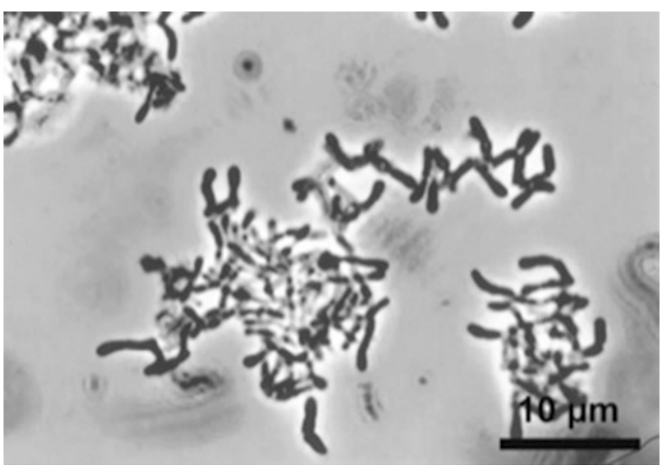

FIGURE 73. Cellular morphology of *Metascardovia criceti* OMB 105^T grown in liquid TPY medium. Phase-contrast photomicrograph (magnification 1500×).

Genus VI. **Parascardovia** Jian and Dong 2002, 811[VP]

Paola Mattarelli and Bruno Biavati

Pa.ra.scar.do′vi.a. Gr. prep. *para* beside, alongside of, near, like; N.L. fem. n. *Scardovia* a bacterial generic name; N.L. fem. n. *Parascardovia* resembling *Scardovia*.

Gram-stain-positive, non-acid-fast. Nonsporeforming. Nonmotile, small, slender rods of variable shape. **Anaerobic**. **Saccharoclastic**. **Glucose is degraded exclusively and characteristically by the fructose 6-phosphate** (F6PPK; EC 4.1.2.22) **shunt** (see treatment of the genus *Bifidobacterium*, above). Fermentation products from glucose are acetic acid and L-(+)-lactic acid in the molar ratio of 2:1. **Dextran is fermented by most strains.** Found in human dental caries and plaque. 16S rRNA and HSP60 gene sequence analyses have shown that the genus *Parascardovia* belongs to the family *Bifidobacteriaceae*. The type and only species is *Parascardovia denticolens*.

DNA G+C content (mol%): 55 ± 1 (T_m).

Type species: **Parascardovia denticolens** (Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996) Jian and Dong 2002, 811[VP] (*Bifidobacterium denticolens* Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996, 570).

Further descriptive information

Phylogeny. See treatment of *Scardovia*, below.

Nutrition. None of the *Parascardovia denticolens* strains studied could grow in a synthetic medium even when all of the amino acids and vitamins were added (Modesto et al., 2003). They are able to grow well when the synthetic medium contains, in addition to the amino acids and vitamins, pantethine (0.15 g/l), pancreatin (0.15 g/l), and lysozyme (0.4 g/l, inactivated by boiling for 10 min), but not when these compounds are added one at a time. For additional information, see treatment of *Scardovia inopinata*.

Ecology. *Bifidobacteriaceae* strains are inhabitants of the oral cavity, but can reach the stomach, although normally they do not survive there due to the acidic conditions. However, under some circumstances, such as stomach achlorydria induced by pharmacological treatments or disease, microbial populations may develop. *Bifidobacterium dentium*, *Parascardovia denticolens*, and *Scardovia inopinata* have been detected in the human achlorydric stomach (unpublished data).

Plasmids. *Parascardovia denticolens* strains do not contain plasmid DNA or produce any band in addition to chromosomal DNA bands (Crociani et al., 1996).

Enrichment and isolation procedures

The procedures for enrichment and isolation of *Parascardovia denticolens* are the same as those described for the genus *Scardovia*.

Maintenance procedures

Parascardovia denticolens can be maintained at −135°C or as freeze-dried cultures by using the standard procedures described for the genus *Bifidobacterium*.

List of species of the genus *Parascardovia*

1. **Parascardovia denticolens** (Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996) Jian and Dong 2002, 811[VP] (*Bifidobacterium denticolens* Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996, 570)

den.ti.co′lens. L. n. *dens*, *dentis* tooth; L. v. *colere* to dwell; L. part. adj. *colens* dwelling; N.L. part. adj. *denticolens* tooth-dwelling.

Small, slender rods (0.8–1.5 μm long), occasionally arranged in V-shapes. Morphology is variable depending on the culture conditions (Figure 74). In the presence of lactose, cells of arabinose-negative strains are very long (4–5 μm), sometimes branched, and have wide ends, whereas those of arabinose-positive strains are smaller and coccoid (0.4–0.6 μm long). At an initial pH of 7.7 or 8.0, cells are very small (0.4–0.6 μm long), but at an initial pH of 4.9 or 5.5 they are longer and branched or short (0.8–2.5 μm long) and frequently club-shaped. In liquid cultures incubated in an air/CO_2 mixture (1:10) at 37°C, much longer rods with swollen ends are formed. However, cells become very long (3–10 μm long) and branched when cultures are incubated

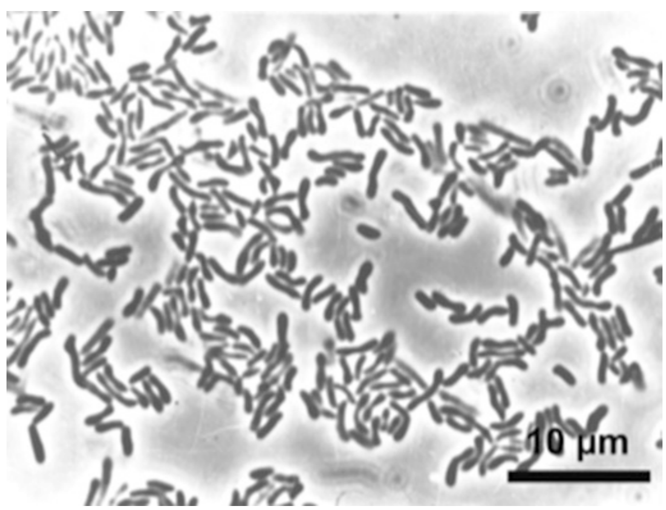

FIGURE 74. Cellular morphology of *Parascardovia denticolens* B3028[T] grown in liquid TPY medium. Phase-contrast photomicrograph (magnification 1500×).

at 30°C, but they are unbranched and flexible with protuberances if grown at 42°C. Liquid cultures of this species always have clear supernatants with compact sediment in clumps that cannot be dispersed with vigorous swirling. Colonies on TPY agar are soft, smooth, circular, convex with irregular margins, glistening, and cream to white. Anaerobic. CO_2 enhances anaerobic growth.

Fermentation products from glucose are L-(+)-lactic acid and acetic acid in the molar ratio of 1:2. The optimal temperature for growth is 36.5–38.5°C; the minimum temperature is 27.0–30.5°C and the maximum temperature is 42–44°C. Growth does not occur at 25 or 46°C, or at pH 4.4 or 8.5.

Amylose, amylopectin, cellobiose, dextrin, fructose, galactose, glucose, inulin, lactose, maltose, melibiose, raffinose, D-ribose, salicin, starch, and sucrose are fermented, but not alginate, arabinogalactan, bovine submaxillary mucin, chondroitin sulfate, D-fucose, L-fucose, D-galactosamine, α-D-galacturonate, D-glucitol, gluconate, D-glucuronate, glycerol, gum arabic, ghatti gum, guar gum, locust bean gum, karaya gum, tragacanth gum, heparin, hyaluronate, lactate, laminarin, D-mannitol, mannose, melezitose, ovomucoid, pectin, polygalacturonate, porcine gastric mucin, L-rhamnose, xylan, or D-xylose. L-Arabinose, D-glucosamine, and trehalose fermentation is variable. Dextran is fermented by 75% of strains.

Acetylmethylcarbinol is produced and asparagine is hydrolyzed. Negative for nitrate reduction, and indole, hydrogen sulfide, catalase, and pseudocatalase (hemin) production. Gelatin is not liquefied. Ammonia is not produced from arginine or urea. Litmus milk is always acidified and coagulated.

Source: found in human dental caries and plaque. In a study on the occurrence of the family *Bifidobacteriaceae*, the prevalence of *Parascardovia denticolens* in human dental caries and plaque was similar (Modesto et al., 2006).

DNA G+C content (mol%): 55 ± 1 (T_m).

Type strain: B3028, CCUG 35728, DSM 10105, LMG 18312, NCTC 12936.

Sequence accession no. (16S rRNA gene): D89331.

Genus VII. **Scardovia** Jian and Dong 2002, 811[VP]

PAOLA MATTARELLI AND BRUNO BIAVATI

Scar.do'vi.a. N.L. fem. n. *Scardovia* named after Vittorio Scardovi, an Italian microbiologist who has made many contributions to our knowledge of bifidobacteria.

Gram-stain-positive, non-acid-fast. Nonsporeforming. Nonmotile, anaerobic, rod-shaped cells that are small and coccoid and of variable shape. Saccharoclastic. Glucose is degraded exclusively and characteristically through the fructose 6-phosphate (F6PPK; EC 4.1.2.22) **shunt** (see treatment of the genus *Bifidobacterium*, above). The products from glucose fermentation are L-(+)-lactic acid and acetic acid in the molar ratio of 1:2.9. **Dextran is fermented.** Found in human dental caries and plaque.

DNA G+C content (mol%): 45 ± 1 (T_m).

Type species: **Scardovia inopinata** (Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996) Jian and Dong 2002, 811[VP] (*Bifidobacterium inopinatum* Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996, 569).

Further descriptive information

Phylogeny. The proposal of the genus *Scardovia* was based primarily on 16S rRNA and HSP60 gene sequence data and the genus is classified in the family *Bifidobacteriaceae*. Bifidobacteria were divided into two subclusters based on 16S rRNA gene sequence data (Miyake et al., 1998). Subcluster 2 encompassed *Bifidobacterium inopinatum* DSM 10107^T and *Bifidobacterium denticolens* DSM 10105^T (another species isolated from dental caries and described by Crociani et al., 1996), whereas subcluster 1 contained all of the other members of the genus *Bifidobacterium* together with *Gardnerella vaginalis*. The 16S rRNA gene sequence similarities to members of subcluster 1 ranged from 90.2 to 91.9% for *Bifidobacterium inopinatum* DSM 10107^T and from 90.7 to 92.8% for *Bifidobacterium denticolens* DSM 10105^T. *Gardnerella vaginalis* ATCC 14018^T, another member of the family *Bifidobacteriaceae* (Stackebrandt et al., 1997), shared higher 16S rRNA gene sequence similarities (91.6–95.3%) to other *Bifidobacterium* species than *Bifidobacterium inopinatum* DSM 10107^T and *Bifidobacterium denticolens* DSM 10105^T. A 16S rRNA phylogenetic tree of the family *Bifidobacteriaceae* is shown in Figure 66.

HSP60 has been used in bacterial phylogenetic analyses (Kwok et al., 1999; Viale et al., 1994). Jian et al. (2001) analyzed the sequence similarities of 538 bp fragments in the highly conserved HSP60 genes of 35 *Bifidobacterium* strains and of *Gardnerella vaginalis* ATCC 14018^T and found that *Bifidobacterium inopinatum* DSM 10107^T, *Bifidobacterium denticolens* DSM 10105^T, and the other *Bifidobacterium* species grouped into three distinct subclusters. *Bifidobacterium inopinatum* DSM 10107^T and *Bifidobacterium denticolens* DSM 10105^T showed exceptionally low levels of similarity to all other members of the genus *Bifidobacterium* (76–80 and 73–78.8%, respectively), whereas all other members exhibited sequence similarities of 81–98%. In the phylogenetic tree, *Gardnerella vaginalis* ATCC 14018^T and *Bifidobacterium inopinatum* DSM 10107^T were assigned to one subcluster, a result in line with DNA base composition data (42 mol% for *Gardnerella vaginalis* ATCC 14018^T and 45 mol% for *Bifidobacterium inopinatum* DSM 10107^T). However, the sequence similarity between *Bifidobacterium denticolens* and *Bifidobacterium inopinatum* was just 79%. *Bifidobacterium inopinatum* and *Bifidobacterium denticolens* were eventually reclassified as *Scardovia inopinata* and *Parascardovia denticolens*, respectively, based on DNA G+C content, 16S rRNA and HSP60 gene sequence analysis, and some phenotypic data (Jian and Dong, 2002).

Cell morphology and phase variations. Crociani et al. (1996) isolated 32 strains that were subsequently classified as *Bifidobacterium inopinatum* from dental caries. These isolates showed unusual phenotypic characteristics, notably a distinct cellular morphology, a characteristic that has significance for this group, and the presence of two types of colonies associated with different cellular morphologies. This latter characteristic has been observed and studied as a phenomenon of phase variation in only one member of the *Bifidobacteriaceae* family, namely *Bifidobacterium animalis* (Biavati et al., 1992a).

Dextran fermentation. Another phenotypic characteristic, also shown by *Parascardovia denticolens*, which distinguishes *Scardovia inopinata* from bifidobacteria is the ability to ferment dextran (Crociani et al., 1994). This feature was observed by Clarke (1959) in a rumen strain that closely resembled bifidobacteria and was therefore named *Lactobacillus bifidus*. Later, Kaster and Brown (1983) isolated three dextran-degrading, F6PPK-positive strains from human dental plaque and assigned them to the genus *Bifidobacterium*, but not to any species because they did not appear to be members of *Bifidobacterium dentium*.

Nutrition. The nutritional requirements of *Scardovia inopinata* and *Parascardovia denticolens* were compared to those of *Bifidobacterium dentium* by Modesto et al. (2003). The *Bifidobacterium dentium* strains showed optimal growth in a synthetic medium supplemented with vitamins, thereby confirming that this species requires pantothenate and riboflavin for growth. The *Scardovia inopinata* and *Parascardovia denticolens* strains also needed vitamins, as well as amino acids for growth. The results obtained with the *Scardovia inopinata* and *Parascardovia denticolens* strains isolated from human dental caries confirmed the observations reported on the nutritional requirements of *Bifidobacterium* species of human origin (Bezkorovainy and Miller-Catchpole, 1989; Tamura, 1983), namely that pantethine, a bifidus factor present in pancreatin and inactivated lysozyme, is indispensable for optimal growth of bifidobacteria of human origin. It can also be hypothesized that: (i) isolates of *Scardovia inopinata* and *Parascardovia denticolens* are unable to use pantothenic acid, the latter supplies a substitute growth factor that is converted within cells to coenzyme A, which is essential for all metabolic pathways; (ii) the growth-promoting effect of pancreatin is probably due either to a bifidus factor or to the presence of some enzymes (lacking in the strains examined) capable of hydrolyzing complex compounds that are otherwise not utilizable by the micro-organisms; and (iii) the inactivated lysozyme by hydrolyzing the polysaccharides of glycoproteins provides simpler nutrients which exert a growth-promoting effect on bifidobacteria. The requirement for lysozyme, a component of saliva, could be as a result of these bacteria living in dental caries

Ecology. A study on the occurrence of members of the family *Bifidobacteriaceae* in the human oral cavity revealed the presence of *Bifidobacterium dentium*, *Scardovia inopinata*, and *Parascardovia denticolens* in dental caries and plaque. *Scardovia inopinata* was more frequently isolated from caries samples than plaque (Modesto et al., 2006).

Pathogenicity. Like other oral micro-organisms, *Bifidobacteriaceae* strains might play a role in promoting the cariogenic process (acid production) and in the reduction of plaque formation (glucanase activity). Recently, in a study on the molecular analysis of bacterial species associated with childhood dental caries, the high incidence of members of the family *Bifidobacteriaceae* has been considered to play a large role in caries pathogenesis (Becker et al., 2002). However, the actual influence of members of this taxon on dental caries is unknown; hence, further studies are needed in order to characterize their role.

Plasmids. *Scardovia inopinata* strains do not contain plasmid DNA or produce any band in addition to chromosomal DNA bands (Crociani et al., 1996).

Enrichment and isolation procedures

Samples removed with sterile tooth-picks from the oral cavity (normally plaque or dental caries) are immediately suspended in 0.5 ml pre-reduced anaerobically sterilized dilution blanks (Holdeman et al., 1977) in 3 ml cryovials. They should then be maintained under anaerobiosis at 4°C. All microbiological analyses should be carried out 1–6 h later. Two slopes of each sample should then be plated on *Bifidobacterium*-selective TPY medium supplemented with 5% propionic acid (pH 5.0) (Beerens, 1990). The inoculated plates should be incubated anaerobically for 5 d at 37°C, then 12–15 randomly picked colonies should be subcultured in 0.5% agar TPY stabs. Identification and characterization assays should be carried out using isolates grown anaerobically in TPY liquid medium at 37°C for 24 h.

Maintenance procedures

Scardovia inopinata can be maintained at −135°C or as freeze-dried cultures by using the standard procedures described for the genus *Bifidobacterium*.

List of species of the genus *Scardovia*

1. **Scardovia inopinata** (Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996) Jian and Dong 2002, 811^{VP} (*Bifidobacterium inopinatum* Crociani, Biavati, Alessandrini, Chiarini and Scardovi 1996, 569)

   in.o.pin.a′ta. L. fem. adj. *inopinata* unexpected, referring to the very unusual morphology.

   An actinomycete which forms very small cocci (0.3–0.6 µm long; Figure 75). Cells become longer and more slender when strains are grown in liquid cultures containing fermentable sugars, such as lactose and raffinose. Much longer cells with swellings (1.3–3.0 µm in length) are produced in the presence of maltose and starch. This micromorphology also occurs on MRS medium and on tomato juice agar. The homogeneous sediment found in liquid cultures can be dispersed easily and never forms clumps.

   Circular, soft, smooth, convex, cream to white colonies with unbroken edges are formed on TPY agar. Two colony types

are produced. O colonies are made up of longer, slightly irregular rods and rarely contain club-shaped cells (Figure 76), whereas T colonies are formed when liquid cultures are incubated in an air/CO_2 mixture (1:10); in this instance, cells are much longer, more flexible, and exhibit wider ends and rare branches (2.0–8.0 µm long). These cells are very similar to those of typical bifidobacteria (Figure 76). Anaerobic. CO_2 enhances anaerobic growth. The fermentation products from glucose are L-(+)-lactic acid and acetic acid in a molar ratio of 1:2.9.

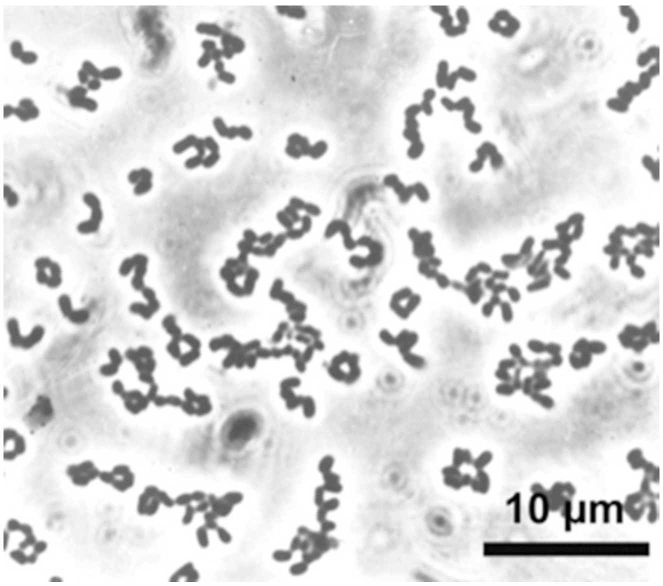

FIGURE 75. Cellular morphology of *Scardovia inopinata* B3109^T grown in liquid TPY medium. Phase-contrast photomicrograph (magnification ×1500).

The optimal temperature for growth is 38.5–42°C; minimum and maximum temperatures are 27–30.5 and 44°C, respectively. Growth does not occur at 26.5 or 46°C. The optimal initial pH is 6.9–7.4; growth is delayed at pH 4.9 and 8.0, and does not occur at pH 4.3 or 8.5.

Amylopectin, α-D-galacturonate, amylose, bovine submaxillary mucin, cellobiose, chondroitin sulfate, dextrin, fructose, glucose, maltose, D-ribose, starch, sucrose, and D-xylose are fermented, but not alginate, arabinogalactan, L-arabinose, D-fucose, L-fucose, D-galactosamine, D-glucitol, D-glucosamine, D-mannitol, glycerol, gluconate, gum arabic, ghatti gum, guar gum, locust bean gum, karaya gum, tragacanth gum, heparin, hyaluronate, lactate, laminarin, mannose, porcine gastric mucin, ovomucoid, pectin, polygalacturonate, L-rhamnose, trehalose, or xylan. Galactose is characteristically not fermented. Fermentation of D-glucuronate, inulin, lactose, melezitose, melibiose, raffinose, and salicin is variable. Thirty out of 31 isolates were found to ferment dextran. Acetylmethylcarbinol is produced and asparagine is hydrolyzed. Nitrate reduction, and indole, hydrogen sulfide, catalase, and pseudocatalase (hemin) production are negative. Gelatin is not liquefied. Ammonia is not produced from arginine or urea. Litmus milk is always acidified and coagulated.

Source: found in human dental caries and plaque. *Scardovia inopinata* was the species most frequently isolated in dental caries compared to dental plaque in a study on the occurrence of members of the family *Bifidobacteriaceae* in human dental caries and plaque (Modesto et al., 2006).

DNA G+C content (mol%): 45 ± 1 (T_m).

Type strain: B3109, CCUG 35729, DSM 10107, LMG 18313, NCTC 12937.

Sequence accession no. (16S rRNA gene): AB029087.

Order IV. **Catenulisporales** ord. nov.

Stefano Donadio, Linda Cavaletti and Paolo Monciardini

Ca.te.nu.li.spo′ra.les. N.L. fem. n. *Catenulispora*, type genus of the order; suff. -*ales*, ending to denote an order; N.L. fem. pl. n. *Catenulisporales*, the *Catenulispora* order.

The order *Catenulisporales* is formed by elevation of the suborder *Catenulisporineae*. The suborder was defined on the basis of phylogenetic analysis of 16S rRNA gene sequences to accommodate the families *Catenulisporaceae* and *Actinospicaceae*. Bootstrap analysis suggests a monophyletic origin for the two families (Figure 77), which also share a common pattern of 16S rRNA gene signatures consisting of nucleotides 127:234 (G–C), 138:225 (U–A), 139:224 (C–G), 140:223 (C–G), 141:222 (A–U), 157:164 (G–C), 449 (C), 589:650 (C–G), 602:636 (R–U), 603:635 (A–U), 694 (G), and 1251 (G).

Type genus: **Catenulispora** Busti, Cavaletti, Monciardini, Schumann, Rohde, Sosio and Donadio 2006, 1745[VP].

Key to differentiating the families of the order *Catenulisporales*

Family *Catenulisporaceae* vs family *Actinospicaceae*:

Chemotaxonomic parameters: LL-Dpm; C_{16} iso, C_{17} anteiso predominant fatty acids; absence of glucosamine-containing phospholipids vs 3-OH-Dpm; C_{15} iso, C_{16} iso, C_{15} ante predominant fatty acids; presence of glucosamine-containing phospholipids.

A subset of 16S rRNA gene signature nucleotides (129:232, U–A vs C–G; 591:648, C–G vs U–R; 952:1229, U–A vs C–G; no nucleotides vs 7–9 extra nucleotides between positions 1134 and 1140).

Physiological parameters: growth vs no growth at pH 6.5.

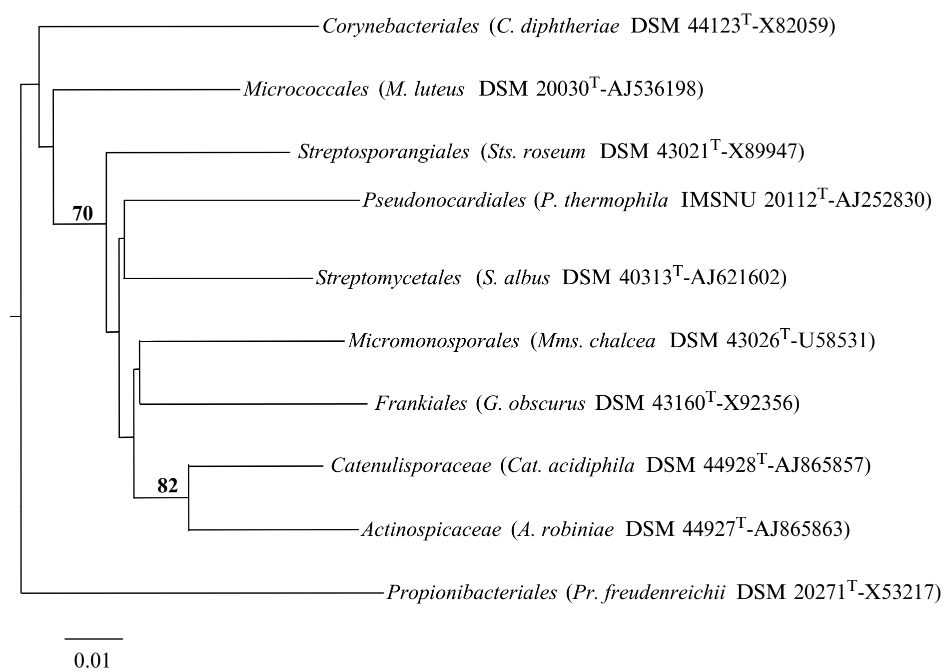

FIGURE 77. Neighbor-joining tree showing the placement of the order *Catenulisporales* families *Catenulisporaceae* and *Actinospicaceae* relative to other orders in the class *Actinobacteria*. For each order, the 16S rRNA gene sequence of the type strain from the type species is used in the alignment, with the exception of the *Frankiales*, for which it is replaced by the type strain of the family *Geodermatophilaceae*. Genus abbreviations are as follows: *A.*, *Actinospica*; *C.*, *Corynebacterium*; *Cat.*, *Catenulispora*; *G.*, *Geodermatophilus*; *M.*, *Micrococcus*; *Mms.*, *Micromonospora*; *P.*, *Pseudonocardia*; *Pr.*, *Propionibacterium*; *S.*, *Streptomyces*; *Sts.*, *Streptosporangium*. The tree is based on 1291 aligned positions within the 16S rRNA gene, omitting regions of ambiguous alignment, and was rooted using the 16S rRNA gene sequence of *Bifidobacterium bifidum* IFO 14252[T] (GenBank S83624). Numbers at nodes are bootstrap values based on 100 resamplings, only values higher than 60 are shown. Scale bar indicates 1 inferred nucleotide substitution per 100 nt.

Ca.te.nu.li.spo.ra.ce′a.e. N.L. fem. n. *Catenulispora* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Catenulisporaceae* the *Catenulispora* family.

The family *Catenulisporaceae* was created to accommodate the genus *Catenulispora* on the basis of phylogenetic analysis of 16S rRNA. Members of the family share a common pattern of 16S rRNA gene signatures, represented by nucleotides 127:234 (G–C), 129:232 (U–A), 449 (C), 580:761 (U–A), 586:755 (U–A), 591:648 (C–G), 824:876 (A–U), 825:875 (A–U), 834:852 (G–U), 838:848 (U–G), 952:1229 (U–A), 999:1041 (U–U), and 1000:1040 (U–U). These signatures are defined on the basis of sequences from the four validly published species and of 7 additional sequences, from strains NEO 1, NEO 2, NEO 6 (Busti et al., 2006b), and strains ELLIN 5116, 5119, 5034, and 5062 (Joseph et al., 2003). The description of the family *Catenulisporaceae* matches that of the type genus.

DNA G+C content (mol%): 69–72.

Type genus: **Catenulispora** Busti, Cavaletti, Monciardini, Schumann, Rohde, Sosio and Donadio 2006a, 1745VP.

Ca.te.nu.li.spo′ra. L. fem. n. *catenula* small chain; Gr. fem. n. *spora* seed and in biology a spore; N.L. fem. n. *Catenulispora* a thin chain of spores.

Stable, extensively-branched vegetative mycelium. Monopodially or dichotomously branched aerial hyphae produced on various media. Rod shaped and nonmotile spores, formed on the aerial mycelium and arranged in straight or flexuous chains, are 0.4–1.2 × 0.5–1.5 μm. Gram-stain-positive. Aerobic and non-acid-fast. **Some species acidophilic**. Optimal temperature is 25–30°C. Peptidoglycan contains **LL-diaminopimelic acid and glycine (A3γ type** *sensu* Schleifer and Kandler, 1972) plus glutamic acid and alanine. Arabinose is common to all, although additional sugars complete the whole-cell sugar pattern in the different species. Predominant menaquinones are MK-9 (H_8), (H_6), (H_4), in different amounts depending on the species. Predominant fatty acids are **saturated C_{16} iso and C_{17} anteiso**. Polar lipids containing glucosamine are not detected. Natural habitat is soil.

DNA G+C content (mol%): 69–72.

Type species: **Catenulispora acidiphila** Busti, Cavaletti, Monciardini, Schumann, Rohde, Sosio and Donadio 2006a, 1745VP.

Further descriptive information

All the described species share a common aerial structure characterized by chains of rod-shaped spores produced on aerial hyphae. The chains are straight or flexuous and spores are nonmotile (Figure 78). Colonies show the typical aspect of actinomycetes, with pigmentations ranging from yellow to red or brownish for the different species. In some cases the same strain shows different pigmentation on the different media used for growth.

Chemotaxonomically, the genus *Catenulispora* represents a homogeneus group in terms of peptidoglycan composition (all contain LL-diaminopimelic acid, glycine, glutamic acid, and alanine), cellular fatty acids (46–67% of $C_{16:0}$ iso and 12–28% $C_{17:0}$ anteiso in the different species), and isoprenoid quinones (all with nine isoprene units and 2, 3, or 4 saturated units), although the latter are present with different relative amounts: *Catenulispora acidiphila* has MK-9(H_6) and -(H_4) as the predominant compounds; *Catenulispora rubra* MK-9(H_6) and -(H_8); and *Catenulispora subtropica* and *Catenulispora yoronensis* MK-9(H_8) and -(H_6), respectively (Table 24). Less homogeneity is present in the polar lipids and especially in the whole-cell sugars pattern. In terms of polar lipids, all species lack glucosamine-containing phospholipids, but *Catenulispora acidiphila* contains phosphatidylglicerol (PG), diphosphatidylglicerol (DPG), phosphatidylinositol (PI), phosphatidylinositol mannosides, and two unknown phospolipids; *Catenulispora rubra* contains PG and PI; and *Catenulispora subtropica* and *Catenulispora yoronensis* contain only DPG. With respect to the whole-cell sugars, *Catenulispora acidiphila* contains arabinose in large amounts plus xylose, ribose, rhamnose, and glucose; *Catenulispora rubra* contains rhamnose, mannose, arabinose, and galactose; *Catenulispora subtropica* and *Catenulispora yoronensis* contain mannose, arabinose, and galactose.

Acidophilia is characteristic only for *Catenulispora acidiphila* and *Catenulispora rubra* as they grow between pH 4.0–4.5 and 6.5 with optima at 6.0 and 5.0, respectively, with the first showing growth even at pH 7.0. On the contrary, the other two species grow well in the pH range 5–7 (optima at 6–7) with *Catenulispora subtropica* able to grow also at pH 8.

Strains are mesophilic but perform best below 30°C, and *Catenulispora acidiphila* does not grow at 40°C.

The genus *Catenulispora* comprises at present four species, one isolated from Italian forest soils (*Catenulispora acidiphila*) and the other three from Japanese forest or paddy soils. Phylogenetically related strains have also been isolated from Australian pasture soils (Joseph et al., 2003). Moreover, 16S rRNA gene sequences belonging to this genus have been amplified from soil DNA isolated from samples of European, American, and African origin (Busti et al., 2006b). This genus can thus be defined as ubiquitous, and new species are expected to be described.

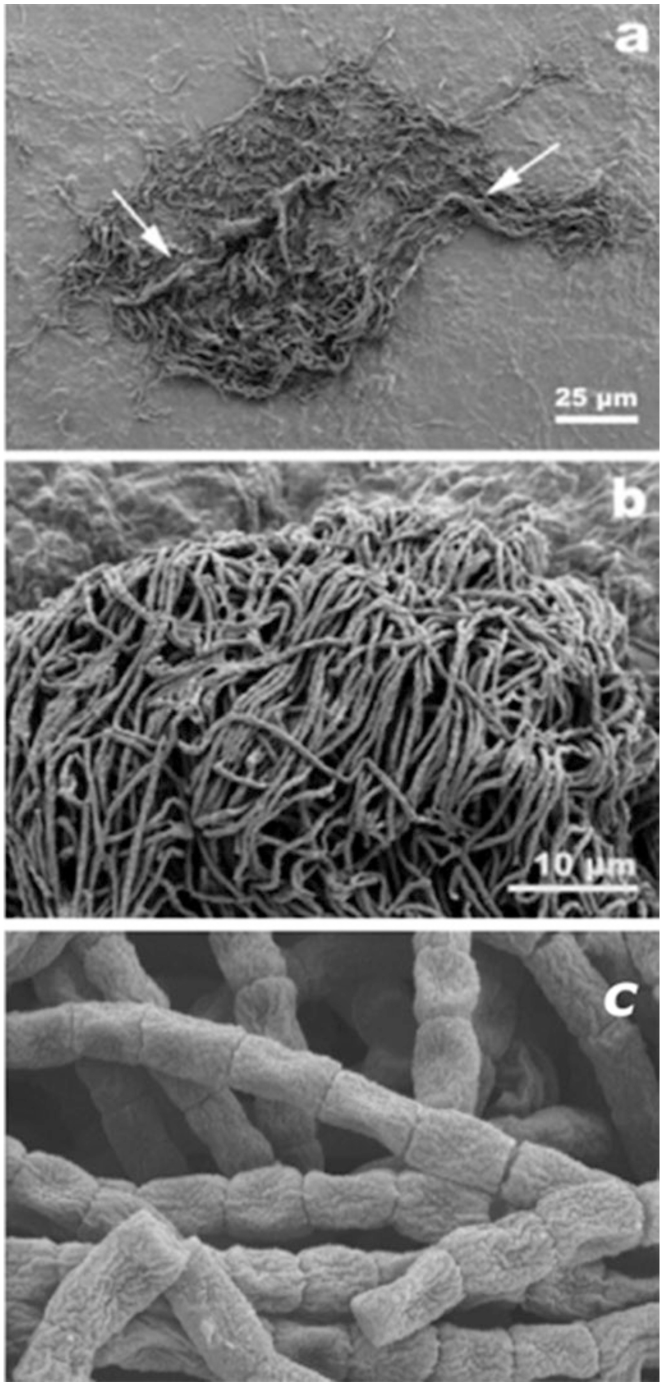

FIGURE 78. Field emission scanning electron microscopy (FESEM) of strain *Catenulispora acidiphila* grown on HSA5 agar for 3 weeks at 28°C. (a) Panoramic view of aerial hyphae. Arrows indicate bundles of hyphae running together. (b) Septation of hyphae gives origin to chains of more than 20 spores. (c) Cylindrical arthrospores (0.4–1.0 µm length × approximately 0.5 µm diameter) with a rugose surface are visible. Collapsing of the central part of spores walls results in a wavy appearance of spore chains as seen in (b).

Enrichment and isolation procedures

Acidic isolation media are useful to enrich for acidophilic strains of the genus *Catenulispora*, while other species can be isolated on neutral media. Moreover, in our experience acidophilic strains of *Catenulispora* can only be retrieved from acidic soils. This finding is consistent with the observation that 16S rRNA gene sequences related to these strains were amplified from one third of the soils with a pH of 5.5, or lower, while no signal was observed from 19 soils with pH >7 (Busti et al., 2006b). Nutrient-poor media, having only soil extract or humic acid as carbon and nitrogen sources, favor the isolation of these organisms.

Catenulispora acidiphila was isolated on GTV agar medium [500 ml/l soil extract (prepared by autoclaving 100 g fresh soil suspended in 500 ml H_2O and filtered through sterile gauze), 10 g/l gellan gum, 3 mM $CaCl_2$, pH 5] supplemented with 0.1% (v/v) CMM vitamin solution (25 µg/ml thiamin hydrochloride, 250 µg/ml calcium pantothenate, 250 µg/ml nicotinic acid, 500 µg/ml biotin, 1.25 mg/ml riboflavin, 6 µg/ml vitamin B_{12}, 25 µg/ml *p*-aminobenzoic acid, 500 µg/ml folic acid, and 500 µg/ml pyridoxal hydrochloride) and 50 µg/ml cycloheximide, after serial dilution of a soil suspension in 18.2 mM citric acid, 164 mM Na_2HPO_4, pH 7. Plates were incubated at 28°C for 8 weeks.

Catenulispora subtropica and *Catenulispora yoronensis* were isolated by pretreating soil suspensions with sodium dodecyl sulfate (SDS)-yeast extract solution (6% yeast extract and 0.05% SDS) at 40°C for 30 min (Hayakawa and Nonomura, 1989) before plating onto humic acid-vitamin agar (Hayakawa and Nonomura, 1987); 1 g/l humic acid, 0.5 g/l Na_2HPO_4, 1.71 g/l KCl, 0.05 g/l $MgSO_4 \cdot 7H_2O$, 0.01 g/l $FeSO_4 \cdot 7H_2O$, 0.02 g/l $CaCO_3$, 18 g/l agar, plus 0.5 mg each of thiamine-HCl, riboflavin, niacin, pyridoxin-HCl, inositol, Ca-pantothenate, *p*-aminobenzoic acid, and 0.25 mg biotin) supplemented with 20 µg/ml nalidixic acid and 200 µg/ml cycloheximide.

Catenulispora rubra was instead isolated on an acidic medium made through mixing 1:1 (v:v) two separately autoclaved media: 8 g/l glucose, 4 g/l Difco yeast extract, 36 g/l agar, pH adjusted to 5.0 with H_2SO_4; and 4 g/l $(NH_4)_2SO_4$, 1 g/l K_2HPO_4, 1 g/l $MgSO_4 \cdot 7H_2O$, 0.2 g/l KCl, final pH approximately 4.

Maintenance procedures

For preservation, organisms can be stored in nutrient broth containing 20% glycerol at −80°C, either as harvested cells from cultures in ATSB medium (17 g/l casitone, 3 g/l soytone, 2.5 g/l glucose, 10 mM 2-[*N*-Morpholino]ethanesulfonic acid, adjusted to pH 5.8 with HCl; Busti et al., 2006a) or as cultures collected directly from acidic ISP-3 medium (see footnote to Table 25). Under these conditions, strains remain viable for at least 12 months. For longer storage, lyophilization is recommended.

Taxonomic comments

Apart from the four described species with validly published names, 16S rRNA gene sequences are available for other isolated strains that appear to be members of the genus *Catenulispora*. Most of these sequences have high identity values and show a common phylogenetic origin, sustained by high bootstrap values (Figure 79). Two lineages of *Catenulispora* can be clearly differentiated in the phylogenetic tree shown in Figure 78, one comprising the two recently described species *Catenulispora subtropica* and *Catenulispora yoronensis*, and the second including the validly published species *Catenulispora acidiphila* and *Catenulispora rubra*, as well as the strains NEO 1, NEO 2, and NEO 6 (Busti et al., 2006b) and ELLIN 5116, 5119, 5034, and 5062 (Joseph et al., 2003). This phylogenetic

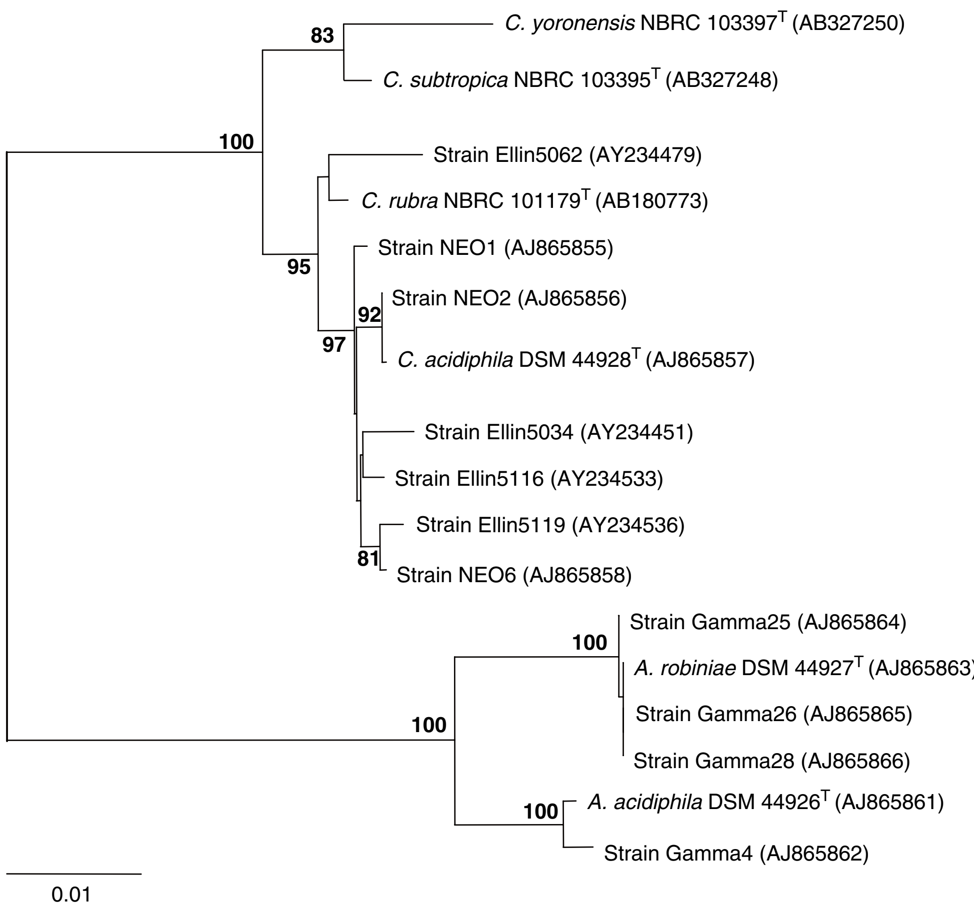

FIGURE 79. Neighbor-joining tree based on 1330 aligned positions within 16S rRNA gene sequences. *C.*, *Catenulispora*; *A.*, *Actinospica*. Sequences from not formally described strains (Busti et al., 2006b; Joseph et al., 2003) are also included. Accession numbers are in parentheses. The tree was rooted using the 16S rRNA gene sequence of *Geodermatophilus obscurus* DSM 43160^T (GenBank X92356). Numbers at nodes are bootstrap values based on 100 resamplings. Only values higher than 80 are shown. Scale bar indicates 1 inferred nucleotide substitution per 100 nt.

differentiation is congruent with physiological and chemotaxonomical differences: *Catenulispora subtropica* and *Catenulispora yoronensis* are not acidophilic while the other strains are; and *Catenulispora subtropica* and *Catenulispora yoronensis* have the same composition of whole-cell sugars and polar lipids pattern, but different from those of the described species of the other lineage. However, the >97% identity levels of the 16S rRNA genes between the two groups and other common chemotaxonomic characteristics are consistent with either a diverse *Catenulispora* genus or with *Catenulispora subtropica* and *Catenulispora yoronensis* belonging to a novel genus within the family *Catenulisporaceae*.

Differentiation of the species of the genus *Catenulispora*

Species of *Catenulispora* can be differentiated by the features summarized in Table 24. Cultural and physiological characteristics of the four species of *Catenulispora* are shown in Table 25 and Table 26 respectively.

List of species of the genus *Catenulispora*

1. **Catenulispora acidiphila** Busti, Cavaletti, Monciardini, Schumann, Rohde, Sosio and Donadio 2006a, 1745[VP]

a.ci.di′phi.la. N.L. n. *acidum* (from L. adj. *acidus* sour) an acid; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *acidiphila* acid-loving.

Stable vegetative mycelium; straight to flexuous, relatively short aerial hyphae produce chains of more than 20 cylindrical arthrospores. Spores are long 0.4–1.0 µm with a mean diameter of about 0.5 µm. Spore surface is rugose. Brown-mahogany soluble pigment produced on tyrosine agar but not on tyrosine-supplemented Suter synthetic medium. Acidophilic, good growth at pH 4.3–6.8, optimum at 6. Mesophilic, best growth at 22–28°C, significant growth at 11 and 37°C, no growth at 4 or 40°C. H_2S produced. Nitrates not reduced. Starch and casein hydrolyzed. Gelatin liquefied. Catalase-positive. Up to 3% (w/v) NaCl is tolerated, as well as 100 µg/ml lysozyme. Glucose, arabinose, xylose, mannitol, fructose, and glycerol are utilized as sole carbon source in acidic ISP-9 whereas sucrose, inositol, rhamnose, and cellulose are not. Resistant to 10 µg/ml nalidixic acid, oxacillin, apramycin, daunomycin, GE2270, nisin, rifampin, and kanamycin, but sensitive to the same concentration of novobiocin, thiostrepton, A40926, and ramoplanin.

Produces metabolites with anti-Gram-stain-positive activity (Busti et al., 2006b).

DNA G+C content (mol%): 71.9 (HPLC).

Type strain: ID139908, DSM 44928, JCM 14897, NBRC 102108, NRRL B-24433.

Sequence accession no. (16S rRNA gene): AJ865857.

2. **Catenulispora rubra** Tamura, Ishida, Sakane and Suzuki 2007, 2273[VP]

ru′bra. L. fem. adj. *rubra* red.

Extensively branched, nonfragmenting vegetative mycelium. Monopodially or dichotomously branched aerial mycelia, sparsely developed; produce straight or flexuous chains of spores. Spores are rod shaped, 0.7–1.5 μm in diameter, nonmotile with a smooth surface. Colonies are red on most media. Acidophilic, growth at pH 4–6.5, optimum at pH 5. Mesophilic, grows at 20–30°C. Nitrates not reduced. Starch and esculin are hydrolyzed, but gelatin or urea are not. Catalase negative. D-Glucose, raffinose, L-arabinose, D-xylose, sucrose, and fructose are used as sole carbon source whereas inositol and rhamnose are not.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: Aac-30, DSM 44948, NBRC 101179.

Sequence accession no. (16S rRNA gene): AB180773.

3. **Catenulispora subtropica** Tamura, Ishida, Otoguro and Suzuki 2008, 1554[VP]

sub.tro.pi.ca. N.L. fem. adj. *subtropica* pertaining to subtropical zone, the origin of the soil sample from which the type strain was isolated.

Extensively and finely branched, nonfragmenting vegetative mycelium. Monopodially or dichotomously branched aerial mycelia develop sparsely. Spores are rod shaped and arranged in rectiflexible or straight chains comprising rod-shaped spores 0.5–0.8 μm in diameter and 0.8–1.2 μm long. Grayish reddish-orange colonies are formed on ISP-2 medium. The pH for growth range is 5–8, and the optimum is 6–7. The temperature for growth range is 10–37°C, and the optimum is 25–30°C. The strain hydrolyzes esculin and gelatin, but not urea. Glycerol, L-arabinose, D-xylose, methyl-β-D-xylopyranoside, D-galactose, D-glucose, D-mannose, *N*-acetyl-glucosamine, arbutin, esculine ferric citrate, salicin, D-celiobiose, D-maltose, starch, glycogen, gentiobiose, L-fucose, and gluconate are used as sole carbon sources. Positive reaction is shown for catalase, nitrate reduction, pyrazinamidase, leucine aminopeptidase, valine aminopeptidase, trypsin, acid phosphatase, phosphohydrolase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase; while negative reaction is shown for pyrrolidonyl arylamidase, esterase (c-4), esterase lipase (c-8), lipase (c-14), cystine aminopeptidase, chymotrypsin, α-galactosidase, and β-glucuronidase.

DNA G+C content (mol%): 70–71 (HPLC).

Type strain: TT 99-48, KCTC 19328, NBRC 103395.

Sequence accession no. (16S rRNA gene): AB327248.

4. **Catenulispora yoronensis** Tamura, Ishida, Otoguro and Suzuki 2008, 1555[VP]

yo.ro.en′sis. N.L. fem. adj. *yoronensis* pertaining to Yoro Valley, Chiba, Japan, the origin of the soil sample from which the type strain was isolated.

Extensively branched substrate hyphae. The vegetative hypha is finely branched and does not fragment. Monopodially or dichotomously branching aerial mycelia develop sparsely. Spores are arranged in rectiflexible or straight chains, rod-shaped, 0.5–0.8 μm in diameter and 0.8–1.2 μm long. They are nonmotile. Light to moderate yellowish brown and/or moderate yellow colonies are formed on ISP-2. Grows at pH 5–7, optimum is 6–7. Growth temperature ranges from 10–37°C, optimum at 25–30°C. Esculin is hydrolyzed, but gelatin and urea are not. D-Xylose, D-glucose, D-mannose, arbutin, esculine ferric citrate, D-celiobiose, D-maltose, D-melibiose, D-trehalose, starch, glycogen, L-fucose, and gluconate are used as sole carbon sources. Positive reaction is shown for catalase, pyrazinamidase, alkaline phosphatase, leucine aminopeptidase, valine aminopeptidase, acid phosphatase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase, while negative reaction is shown for nitrate reduction, pyrrolidonyl arylamidase, esterase (c-4), esterase lipase (c-8), lipase (c-14), cystine aminopeptidase, trypsin, chymotrypsin, β-galactosidase, and β-glucuronidase.

Contrary to the family signatures, nucleotides 586:755 of the 16S rRNA gene are C–G and not U–A.

DNA G+C content (mol%): 69 (HPLC).

Type strain: TT N02-20, KCTT 19327, NBRC 103397.

Sequence accession no. (16S rRNA gene): AB327250.

Family II. **Actinospicaceae** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1751^VP

Stefano Donadio, Linda Cavaletti and Paolo Monciardini

Ac.ti.no.spi.ca.ce′a.e. N.L. fem. n. *Actinospica* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Actinospicaceae* the *Actinospica* family.

The family contains the single genus *Actinospica* and was defined on the grounds of its clear phylogenetic distance from all other actinomycete families. A distinctive pattern of 16S rRNA gene signatures is present, consisting of nucleotides 127:234 (G–C), 129:232 (C–G), 344 (G), 449 (C), 450:483 (C–G), 560 (U), 576 (G), 590:649 (C–G), 591:648 (U–R), 859 (G), 952:1229 (C–G), 1122:1151 (G–C), 1123:1150 (U–G), 1124:1149 (A–U), and of 7–9 extra nucleotides between positions 1134 and 1140.

DNA G+C content(mol%): 69–71 (HPLC).

Type genus: **Actinospica** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1751^VP.

Genus I. **Actinospica** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1751^VP

Stefano Donadio, Linda Cavaletti and Paolo Monciardini

Ac.ti.no.spi′ca. Gr. n. *aktis -inos* a ray; L. fem. n. *spica* tuft; N.L. fem. n. *Actinospica* an actinomycete with tufts of aerial hyphae.

Strains produce nonfragmenting vegetative mycelium and aerial mycelium appearing as tufts of straight to slightly flexuous hyphae, at maturity carrying chains of cylindrical spores with a slightly rugose surface. Chains contain up to 30 (or more) spores. Tufts originate from very short sporophorous hyphae branching in few sporogenous hyphae (Figure 80 and Figure 81). Spores are not motile.

Diagnostic diaminoacid of the peptidoglycan is 3-hydroxydiaminopimelic acid, in addition to glycine, glutamic acid, and alanine. Only small traces of *meso*-diaminopimelic acid are detected.

Predominant fatty acids are **saturated C_{15} iso, C_{16} iso and C_{15} anteiso**. The major menaquinones are MK-9(H_4), MK-9(H_6), and MK-9(H_8). Gram-stain-positive. Aerobic. They are **obligate acidophiles**, growth occurs at pH not exceeding 6.2, optimum at 5.0–5.5. Temperature range for growth is 17–33°C, optimum at 22–28°C. Strains are catalase positive, produce H_2S, are negative for nitrate reduction, gelatin liquefaction, and tyrosine reaction.

DNA G+C content (mol%): 69–71 (HPLC).

Type species: **Actinospica robiniae** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1752^VP.

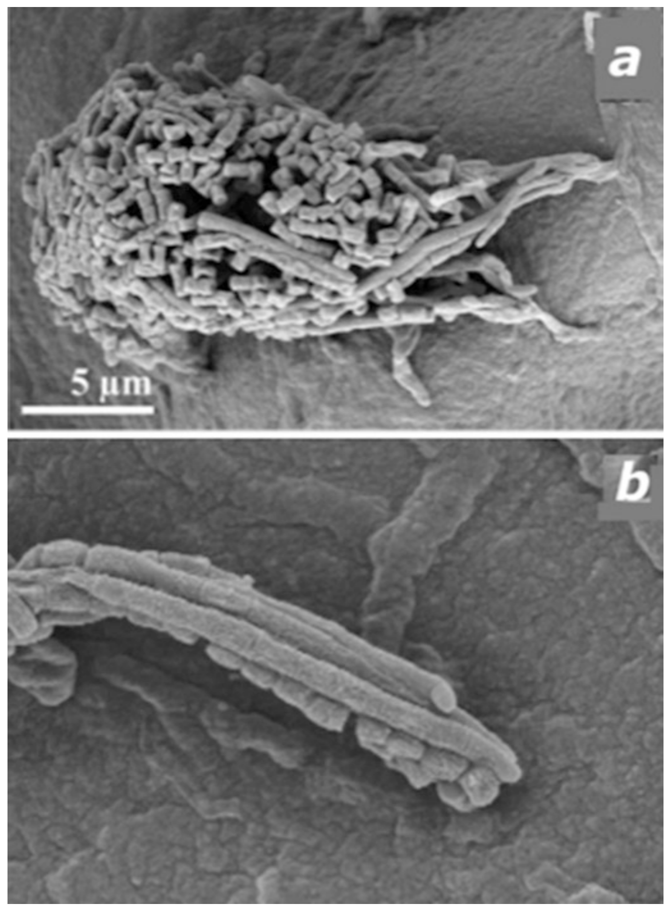

FIGURE 80. Field emission scanning electron microscopy of *Actinospica acidiphila* grown on HSA5 agar for 3 weeks at 28°C. (a) Conic tufts of sporogenous aerial hyphae originated by the branching of single and short sporophorous hyphae can be seen. (b) A young, unseptated hypha runs together with a partially septated one and with a mature one, divided into a spore chain. Panel (b) is from Cavaletti et al. (2006).

Further descriptive information

Strains grow on various agar media, but only at acidic pH, with *Actinospica acidiphila* slightly more acidophilic than *Actinospica robiniae* (Table 27). Cell-wall sugars comprise mannose and rhamnose plus additional sugars differentiating the species (see Table 27). Ratios of the major menaquinones MK-9(H_4), MK-9(H_6), and MK-9(H_8) vary according to the species (23:40:20 and 2:25:59 for *Actinospica acidiphila* and *Actinospica robiniae*, respectively). The polar lipids pattern is common to both species and consists of diphosphatidylglycerol, phosphatidylethanolamine, methyl-phosphatidylethanolamine, and phosphatidylinositol. Glucosamine-containing phospholipids are also present. Production of metabolites with antibiotic activity for strains of this genus (Busti et al., 2006b).

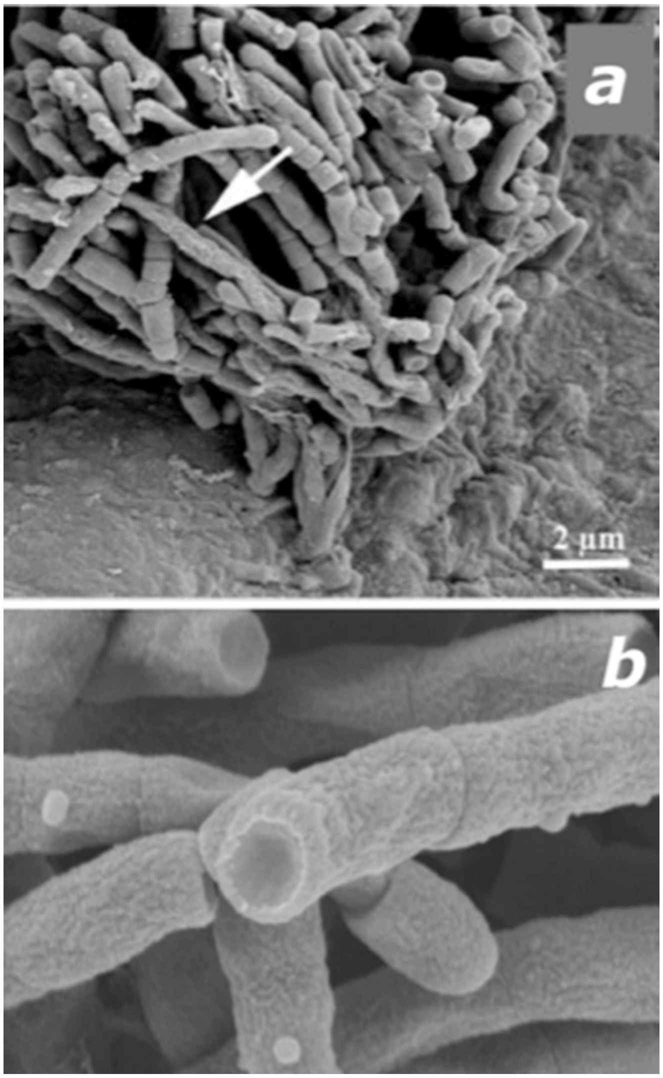

FIGURE 81. Field emission scanning electron microscopy of *Actinospica robiniae* grown on HSA5 agar for 3 weeks at 28°C. (a) Tufts of sporogenous aerial hyphae undergoing division into squat to cylindrical arthrospores are shown. Branching of sporophorous hyphae giving origin to tufts appears very close to the agar surface. Arrow indicates the rugosity of the surface of a hypha that is not fragmented. (b) Cylindrical spores with slightly rugose surface. Panel (b) is from Cavaletti et al. (2006).

Enrichment and isolation procedures

Described strains can be isolated after prolonged incubation on acidified HSA5 medium [0.5 g/l humic acid, 1 mg/l $FeSO_4 \cdot 7H_2O$, 1 mg/l $MnCl_2 \cdot 4H_2O$, 1 mg/l $ZnSO_4 \cdot 7H_2O$, 1 mg/l $NiSO_4 \cdot 6H_2O$, 10 mM 2-*N*-cyclohexyl-2-aminoethanesulfonic acid, 20 g/l agar; adjusted to pH5.5 with HCl, autoclaved, and then supplemented with 0.1% (v/v) CMM vitamin solution (see recipe in the *Catenulispora* chapter, above)] (Busti et al., 2006a) and transferred to acidified ISP-3 (see footnote to Table 25) medium for maintenance.

TABLE 27. Characteristics differentiating species of the genus *Actinospica*[a]

Characteristic	*A. robiniae*	*A. acidiphila*
Tolerance to 1% NaCl	–	+
Optimal pH	5.5	5
Whole-cell sugars	Mannose, rhamnose, galactose	Mannose, rhamnose, arabinose, xylose
Starch hydrolysis	–	+
DNA G+C content (mol%)	70.8	69.2

[a]Symbols: +, positive; –, negative.

Maintenance procedures

For preservation, organisms can be stored in nutrient broth containing 20% glycerol at –80°C, both as harvested cells from cultures in ATSB (17 g/l casitone, 3 g/l soytone, 2.5 g/l glucose, 10 mM 2-[*N*-Morpholino]ethanesulphonic acid, adjusted to pH 5.8 with HCl) medium (Busti et al., 2006a), or as cultures collected directly from acidic ISP-3 medium. Under these conditions, strains remain viable for at least 12 months. For longer storage, lyophilization is recommended.

Taxonomic comments

Although only two species are published with validated names, several 16S rRNA gene sequences with >97% identity to *Actinospica robiniae* and *Actinospica acidiphila* are available in public databases suggesting that the corresponding strains belong to the *Actinospica* genus. The pattern of signature nucleotides for the family is actually defined based on a set that, in addition to those of the two validly described species, contain other 28 sequences from cultured but not formally described strains. These strains were isolated from samples collected in several locations all over the world, indicating a ubiquitous distribution of *Actinospica*.

Differentiation of the species of the genus *Actinospica*

Species of *Actinospica* can be differentiated by the features summarized in Table 27.

Cultural characteristics of the two *Actinospica* species are shown in Table 28.

List of species of the genus *Actinospica*

1. **Actinospica robiniae** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1752[VP]

ro.bi.ni'a.e. N.L. fem. n. *Robinia* scientific name of a genus; N.L. fem. gen. n. *robiniae* of *Robinia*, isolated from a wood of *Robinia pseudoacacia*.

Stable vegetative mycelium. Aerial mycelium appears as enlarged tufts of sporogenous aerial hyphae that upon division form chains of arthrospores (squat to cylindrical, 0.6–0.7 to 1–1.2 × 0.6 µm) with slightly rugose surface. Grows only at acidic pH in the range 4.8–6.2, with optimal growth at pH 5.5. Grows in the range 17–33°C; optimal temperature for growth is in the range 22–28°C; no growth occurs at 14 or 37°C. Does not hydrolyze starch. NaCl at 1% (w/v) significantly inhibits growth. The type strain contains galactose as additional whole-cell sugar.

TABLE 28. Cultural characteristics of *Actinospica* species[a]

Medium[b]/characteristic	*A. robiniae*	*A. acidiphila*
ISP-2:		
Growth	Good	Good

[a] na, Not applicable.

[b] Media according to Shirling and Gottlieb (1966), with pH adjusted to 4.8–5.5 with HCl (see footnote to Table 25, chapter *Catenulispora* for description).

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: GE134769, DSM 44927, JCM 14908, NBRC 102112, NRRL B-24432.

Sequence accession no. (16S rRNA gene): AJ865863.

2. **Actinospica acidiphila** Cavaletti, Monciardini, Schumann, Rohde, Bamonte, Busti, Sosio and Donadio 2006, 1752[VP]

a.ci.di′phi.la. N.L. n. *acidum* (from L. adj. *acidus* sour) an acid; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *acidiphila* acid-loving.

Stable vegetative mycelium. The aerial mycelium appears as tufts of straight to slightly flexuous hyphae which at maturity carry long chains of up to 30 cylindrical spores, occasionally more. Spores are 0.6–0.8 × 0.5 µm in size and have a rugose surface. Grows only at acidic pH in the range 4.2–6.0, with optimal growth at pH 5.0. Temperature optimum for growth is 28°C; grows in the range 17–33°C; no growth at 14°C or 37°C. The strain hydrolyzes starch. NaCl at 1% (w/v) does not affect growth, while at 2% (w/v) it is not tolerated. The type strain contains arabinose and xylose as additional whole-cell sugars.

DNA G+C content (mol%): 69.2 (HPLC).

Type strain: GE134766, DSM 44926, JCM 14896, NBRC 102107, NRRL B-24431.

Sequence accession no. (16S rRNA gene): AJ865861.

Order V. **Corynebacteriales** ord. nov.

Michael Goodfellow and Amanda L. Jones

Co.ry.ne.bac.te.ri'a.les. N.L. neut. n. *Corynebacterium* type genus of order; suff. *-ales* ending to denote order; N.L. fem. pl. n. *Corynebacteriales* the *Corynebacterium* order.

Aerobic or facultatively anaerobic, Gram-stain-positive, catalase-positive actinomycetes which may form a branched substrate mycelium that fragments into coccoid- to rod-shaped elements or present as branched filaments, cocci, or as pleomorphic forms. Chemoorganotrophic. Some strains form aerial hyphae. **The wall peptidoglycan contains *meso*-diaminopimelic acid and is of the A1γ type. Arabinose and galactose are major wall sugars. Fatty acid profiles are rich in saturated and unsaturated components and usually contain tuberculostearic acid. Typically contain mycolic acids.** The pattern of 16S rRNA signatures consists of nucleotides at positions 127:134 (G–Y), 564 (C), 672:734 (U–G), 833:835 (U–G), 952:1229 (U–A), and 986:1219 (U–A). Forms a distinct monophyletic branch in the 16S rRNA actinobacterial gene tree.

The order encompasses the families *Corynebacteriaceae* Lehmann and Neumann 1907 emend. Zhi et al. 2009; *Dietziaceae* Rainey et al. 1997 emend. Zhi et al. 2009; *Gordoniaceae* Rainey et al. 1997; *Mycobacteriaceae* Chester 1897 emend. Zhi et al. 2009; *Nocardiaceae* Castellani and Chalmers 1919 emend. Zhi et al. 2009; *Segniliparaceae* Butler et al. 2005 emend. Zhi et al. 2009; *Tsukamurellaceae* Rainey et al. 1997 emend. Zhi et al. 2009; and the genera *Hoyosella* Jurado et al. 2009; *Tomitella* Katayama et al. 2010; and *Turicella* Funke et al. 1994.

Members of the order are found in diverse environments, notably in the soil ecosystem. Some strains are serious pathogens of humans and domesticated animals.

Type genus: **Corynebacterium** Lehmann and Neumann 1896, 350[AL] emend. Bernard, Wiebe, Burdz, Reimer, Ng, Singh, Schindle and Pacheco 2010, 877.

Further descriptive information

Phylogeny. Until recently, actinomycetes with *meso*-diaminopimelic acid (*meso*-A_2pm), arabinose, and galactose in the peptidoglycan (wall chemotype IV *sensu* Lechevalier and Lechevalier (1970a, 1970b) were assigned to two distinct aggregate groups (Goodfellow, 1992; Goodfellow and Lechevalier, 1989; Goodfellow and Minnikin, 1984). Wall chemotype IV actinomycetes that contain mycolic acids (high-molecular-weight 3-hydroxy fatty acids with a long branch in the 2-position) were assigned to the genera *Corynebacterium*, *Dietzia*, *Gordonia*, *Mycobacterium*, *Nocardia*, and *Tsukamurella* in the suborder *Corynebacterineae* Stackebrandt et al. 1997 and most of their mycolateless counterparts to the suborder *Pseudonocardineae* (Warwick et al., 1994) Stackebrandt et al. 1997. The group of mycolic acid-containing actinomycetes encompassed a few species which appear to have lost the capacity to synthesize mycolates, including *Turicella otitidis*, the type species of the monospecific genus *Turicella* (Funke et al., 1993, 1994).

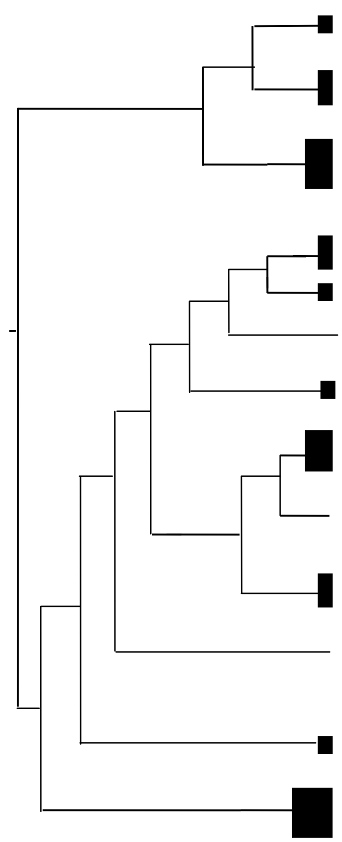
Mycolic acid-containing strains were found to have many phenotypic properties in common (Goodfellow and Cross, 1984; Goodfellow and Wayne, 1982) and formed a recognizable suprageneric group (Mordarski et al., 1980; Stackebrandt and Woese, 1981; Stackebrandt et al., 1980). In addition, representative strains were seen to be closely related using serological techniques (Magnusson, 1976; Pier, 1984), notably immunological procedures which showed the presence of common precipitinogens among corynebacteria, gordoniae, mycobacteria, nocardiae, and rhodococci (Lind et al., 1980; Lind and Ridell, 1976).

The suborders *Corynebacterineae* and *Pseudonocardineae* have been recast in this volume into the orders *Corynebacteriales* and *Pseudonocardiales*, respectively. The order *Corynebacteriales* contains the established mycolic acid-containing genera (Goodfellow and Maldonado, 2006; Stackebrandt et al., 1997) and the recently described taxa *Millisia* Soddell et al. 2006, *Segniliparius* Butler et al. 2005, *Skermania* Chun et al. 1997, *Smaragdicoccus* Adachi et al. 2007, *Tomitella* Katayama et al. 2010, and *Williamsia* Kämpfer et al. 1999. It is becoming increasingly apparent that the order provides a home for a range of mycolateless wall chemotype IV taxa including the genera *Amycolicococcus* Wang et al. 2010 and *Hoyosella* Jurado et al. 2009. Corynebacteria that lack mycolic acids have been assigned to several species including *Corynebacterium amycolatum* Collins et al. 1988a, *Corynebacterium atypicum* Hall et al. 2003, *Corynebacterium capsum* Collins et al. 2004, *Corynebacterium ciconiae* Fernández-Garayzábal et al. 2004, *Corynebacterium kroppenstedtii* Collins et al. 1998, which form distinct phyletic lines in the 16S rRNA *Corynebacterium* tree. Members of the species *Corynebacterium amycolatum* encompass strains previously were misidentified as *Corynebacterium minutissimum*, *Corynebacterium striatium*, and *Corynebacterium xerosis* (Funke et al., 1996; Wauters et al., 1996; Zinkernagel et al., 1996).

Initially, the genera *Corynebacterium*, *Mycobacterium*, and *Nocardia* were assigned to the families *Corynebacteraceae* Lehmann and Neumann 1907, *Mycobacteraceae* Chester 1897, and *Nocardiaceae* Castellani and Chalmers 1919, respectively, based on morphological and staining properties. The composition of these taxa varied over time as classifications were generated using different combinations of phenotypic properties, especially chemotaxonomic and morphological features (Bergey et al., 1939; Goodfellow and Magee, 1998; Lechevalier and Lechevalier, 1970a, 1970b; McClung, 1974). In contrast, mycolic acid-containing genera are now assigned to families based on 16S rRNA gene sequence similarity values and taxon specific 16S rRNA signature nucleotides (Stackebrandt et al., 1997; Zhi et al., 2009). In general, the taxonomic integrity of these families is underpinned by the discontinuous distribution of some chemical markers, as shown in Figure 82.

The current assignment of mycolic acid-containing genera to families is a marked improvement on earlier taxonomies of the group, but even so present classifications need to be seen as part of a progression towards better classifications in the future. It is already clear that the current classification needs to be reassessed with the recognition of novel taxa, as exemplified by the assignment of the mycolateless genus *Amycolicococcus* to the family *Mycobacteriaceae* (Wang et al., 2010). In addition, further comparative taxonomic studies are needed to establish family assignments for the genera *Hoyosella* (Jurado et al., 2009), *Tomitella* (Katayama et al., 2010), and *Turicella* (Funke et al., 1994).

Suprageneric relationships based on 16S rRNA sequence data



Family/genus	Fatty acid pattern[a]	Mycolic acids: Overall size (no. of carbons)[b]	Mycolic acids: Fatty acids released on pyrolysis[b]	Major menaquinones[c]	Phospholipid type[d]

FIGURE 82. Chemotaxonomic profiles of genera and families of wall chemotype IV actinomycetes, including *Segniliparus*, classified in the order *Corynebacteriales*. Symbols: [a]Fatty acid classification according to Kroppenstedt (1985). Numbers refer to the type of fatty acid biosynthetic pathway and letters to the types of fatty acids (FA) synthesized. Type 1, pathway generating straight-chain fatty acids, including saturated and unsaturated (FA-type 1a), 10-methyl-branched (FA-type 1b), and cyclopropane fatty acids (FA-type 1c), the latter two being derived from the unsaturated compounds. Type 2, pathway yielding terminally-branched fatty acids (FA-type 2), i.e. iso- and anteiso-branched fatty acids. Type 3 encompasses organisms that have complex branched fatty acid types, i.e., both 10-methyl-branched (type 1) and iso- and/or anteiso-branched (type 2) fatty acids. [b]Mycolic acid size (number of carbons) and fatty acids released on pyrolysis were detected by the use of GC-MS and MS (Chun et al., 1997). [c]MK-9(H_8), notation for octahydrogenated menaquinone with nine isoprene units. [d]Characteristic phospholipids: PI, nitrogenous phospholipids absent (with phosphatidylglycerol variable); PII, only phosphatidylethanolamine (Lechevalier et al., 1977; Lechevalier et al., 1981). [e]The wall chemotype of *Segniliparus* has still to be established.

Chemotaxonomy. Chemical characterization of actinomycete cells provides invaluable data for the delineation of suprageneric groups such as the orders *Corynebacteriales* and *Pseudonocardiales*, and for the recognition of genera encompassed by them (Goodfellow and Maldonado, 2006; Katayama et al., 2010; Minnikin and Goodfellow, 1980; Minnikin et al., 1978; Wang et al., 2010). The most useful chemical markers for the classification of wall chemotype IV actinomycetes have been obtained from analyses of cellular fatty acids, menaquinones, mycolic acids, polar lipids, wall peptidoglycans, and DNA base composition (Collins, 1994; Embley and Wait, 1994; Goodfellow and Magee, 1998; Kroppenstedt, 1985; Minnikin and Goodfellow, 1976; Schleifer and Kandler, 1972; Schleifer and Seidl, 1985; Suzuki et al., 1994; Uchida et al., 1999). Some of these analyses have provided qualitative information, as exemplified by the detection of mycolic acid and polar lipid patterns, whereas others have yielded quantitative data, as in the case of cellular fatty acid and menaquinone analyses. The detection of variations in the structures, chain lengths, and degree of unsaturation of mycolic acids have proved to be especially useful in the delineation of mycolic acid-containing genera (Goodfellow et al., 1998, 1999; Goodfellow and Maldonado, 2006; Goodfellow and Magee, 1998; Katayama et al., 2010; Minnikin et al., 1980, 1984a, 1984b, 1984c). It is now known that mycolic acids are involved in the formation of an outer cellular membrane that has a bilayer structure (Hoffmann et al., 2008; Zuber et al., 2008).

The chemical profiles of genera assigned to the families which encompass mycolic acid-containing actinomycetes are shown in Figure 82. The genera classified in the families *Gordoniaceae*, *Mycobacteriaceae*, *Nocardiaceae*, and *Tsukamurellaceae* contain *N*-glycolated muramic acid (Uchida and Aida, 1977, 1979a, 1979b), a phospholipid pattern which includes diphosphatidylglycerol,

phosphatidylethanolamine (taxonomically significant nitrogenous phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides (phospholipid type II *sensu* Lechevalier et al., (1977, 1981) and a fatty acid profile rich in straight-chain, unsaturated, and tuberculostearic acids (Kroppenstedt, 1985), but can be distinguished on the basis of menaquinone composition and the overall chain length of mycolic acids. The genera assigned to the families *Corynebacteriaceae* and *Dietziaceae* can be distinguished on this basis but are united in having a peptidoglycan containing *N*-acetylated muramic acid. In turn, members of the genus *Segniliparus* of the family *Segniliparaceae* are characterized by the presence of multiple chemical functional groups of high-molecular-weight, non-polar mycolic acids (Butler et al., 2005). *Tomitella* strains cannot be readily assigned to any of the mycolic acid-containing families but have a chemotaxonomic profile that distinguishes them from genera assigned to these families (Figure 82). Additional chemotaxonomic properties of the mycolic acid-containing genera are shown in Table 29.

The chemotaxonomic profiles of wall chemotype IV genera which lack mycolic acids are shown in Table 30. All of the genera contain unsaturated menaquinones, *N*-acetylated muramic acid moieties, and a combination of chemical markers which distinguish them from mycolic acid-containing taxa. It is interesting that the type strain of *Hoyosella altamirensis* has a DNA G+C content of 49.3 mol%, the lowest recorded value among all of the taxa classified in the order *Corynebacteriales* (Jurado et al., 2009). Little is known about the chemotaxonomic properties of mycolateless members of the genus *Corynebacterium*; these organisms are rich in saturated and unsaturated fatty acids though only *Corynebacterium kroppenstedtii* contains tuberculostearic acid (Collins et al., 1998; Fernández-Garayzábal et al., 2004; Hall et al., 2003). Ultrarapid pyrosequencing of *Corynebacterium kroppenstedtii* DSM 44385^T indicates that its inability to synthesize mycolic acids may be due to gene loss, including a condensase gene cluster and a mycolate reductase gene (Tauch et al., 2008). *Corynebacterium amycolatum* synthesizes unsaturated menaquinones with nine isoprene units and can thereby be distinguished from *Corynebacterium kroppenstedii* which has corresponding menaquinones, albeit with eight isoprene units like *Hoyosella altamirensis* (Jurado et al., 2009).

Lipoglycans found in the walls of some actinomycetes have been assigned to a number of structural archetypes (Sutcliffe, 1995). The most extensively studied lipoglycans are the mycobacterial lipoarabinomannans (Bricken et al., 2004; Chatterjee and Khoo, 1998; Nigou et al., 2003). However, lipoarabinomannans (LAM) and LAM-like/lipomannan components have been extracted and characterized from other mycolic acid-containing taxa including *Corynebacterium diphtheriae* (Moreira et al., 2008), *Dietzia maris* (Sutcliffe, 2000), *Gordonia rubripertincta* (Flaherty and Sutcliffe, 1999), *Rhodococcus equi* (Garton et al., 2002), *Rhodococcus ruber* (Gibson et al., 2003a), and *Tsukamurella paurometabola* (Gibson et al., 2004), and mycolateless *Amycolatopsis sulfurea* (Gibson et al., 2003b), *Lechevalieria aerocolonigenes* (Gibson et al., 2005), and *Turicella otitidis* (Gilleron et al., 2005). Consequently, it is clear that the distribution of the LAM family of lipoglycans is not limited to mycolic acid-containing genera.

The cell walls of some mycolic acid-containing actinomycetes contain one or more cell-wall channels (Lichtinger et al., 2000, 2001, 2004; Riess et al., 1998; Trias et al., 1992). These channels allow the uptake of hydrophilic solutes through the thick mycolic acid layers which form an effective permeability barrier on the outer surface of cells (Brennan and Nikaido, 1995; Jarlier and Nikaido, 1994) that is analogous to the outer membrane of Gram-stain-negative bacteria. There is evidence that the cell wall of *Corynebacterium amycolatum* contains sufficient lipids to form a permeability barrier on the outer wall surface, thereby accounting for the presence of channel-forming proteins in this organism (Dörner et al., 2009). There are grounds for believing that *Micromonospora purpurea* and *Streptomyces griseus* contain cell-wall channels with properties similar to those of mycolic acid-containing genera (Kim et al., 2002).

Detection of chemotaxonomic markers

Members of genera and families classified in the order *Corynebacteriales* can be distinguished from one another and from corresponding taxa in the phylum *Actinobacteria* by 16S rRNA similarity values and by taxon-specific 16S rRNA oligonucleotide sequences (Stackebrandt et al., 1997; Zhi et al., 2009). However, actinobacterial phylogenies need to be supported by additional evidence, as phylogenetic relationships are not always sufficiently robust to allow groups to be delineated with confidence (Labeda et al., 2011) while major differences can be found in actinobacterial trees based on different algorithms (e.g. Ludwig and Klenk, 2005; Zhi et al., 2009).

Chemical markers have provided an effective way of evaluating actinobacterial phylogenies as they are discontinuously distributed across taxa, as exemplified in Figure 82 and Table 29 and Table 30. Standard chemotaxonomic procedures are available for the detection of wall diamino acids (Hancock, 1994; Staneck and Roberts, 1974), fatty acids (Kroppenstedt, 1985; Suzuki and Komagata, 1983) including mycolic acids (Minnikin et al., 1975, 1980), menaquinones (Collins, 1994; Kroppenstedt, Collins, 1982, Collins, 1985; Minnikin et al., 1984a), muramic acid residues (Uchida and Aida, 1977, 1979a, 1979b; Uchida et al., 1999), and polar lipids (Minnikin et al., 1977, 1984a; Tindall, 1990).

Examination of whole-organism hydrolysates for the presence of *meso*-A_2pm, arabinose, and galactose, and the detection of mycolic acids in whole-cell methanolysates are the first steps in the chemotaxonomic procedure. The thin-layer-chromatographic (TLC) procedures of Staneck and Roberts (1974) provide an easy way of detecting the diagnostic amino acid and sugar markers, while mycolic acids can be detected using the acid methanolysis protocol described by Minnikin et al. (1975); modification of these procedures are described in detail by Goodfellow (1996).

The detection of *meso*-A_2pm, arabinose, galactose, and mycolic acids serves to distinguish *Corynebacteriales* strains from corresponding taxa such as the orders *Actinopolysporiales*, *Calenulosporiales*, *Micrococciniales*, *Micromonosporiniales*, *Pseudonocardiales*, *Streptomycetiales*, and *Streptosporangiales*. The mycolateless wall chemotype IV genera *Amycolicicoccus*, *Hoyosella*, and *Turicella* can be distinguished from corresponding actinomycetes classified in the order *Pseudonocardiales* as they contain unsaturated menaquinones (Table 30); a variety of chromatographic procedures can be used to establish menaquinone profiles (Collins, 1994; Minnikin et al., 1984a). The menaquinone composition of most corynebacteria which lack mycolic acids has still to be established.

TABLE 29. Characteristics of wall chemotype IV genera, including *Segniliparus*[a], classified in the *Corynebacteriales*[b]

Characteristic	*Corynebacterium*	*Dietzia*	*Gordonia*	*Millisia*	*Mycobacterium*	*Nocardia*	*Rhodococcus*	*Segniliparus*	*Skermania*	*Smaragdicoccus*	*Tomitella*	*Tsukamurella*	*Williamsia*
Cell morphology	Pleomorphic rods, often club-shaped; commonly in angular and palisade arrangement	Short rods and cocci	Rods and cocci or moderately branching hyphae	Rudimentary right angled branching	Rods, occasionally branched filaments which fragment into rods and coccoid elements	Mycelium which fragments into rods and cocci	Rods to extensive substrate mycelium which fragments into irregular rods and cocci	Rods	Mycelium resembling a pine tree	Coccoid cells	Irregular rods that exhibit snapping division; cells turn to short coccoid rods after prolonged culture	Rods occur singly, in pairs, or in masses; cocobacillary forms occur	Thin irregular rods or cocci occur singly or in small clusters
Aerial hyphae	Absent	Absent	Absent	Present	Usually absent	Present	Absent	Absent	Present but not visible to the naked eye	Absent	Absent	Absent	Present
Time to growth of visible colonies (d)	1–2	1–3	1–3	1–3	2–40	1–5	1–3	3–4	9–21	7	nd	1–3	1–4
Acid-fastness	Sometimes weakly acid-fast	Not acid-fast	Partially acid–alcohol-fast	Acid–alcohol-fast	Strongly acid-fast	Partially acid fast	Partially acid-fast at some stage of the growth cycle	Acid–alcohol-fast	Not acid fast	nd	nd	Partially acid–alcohol-fast	nd
Strictly aerobic	–	+	+	+	+	+	+	+	–	+	+	+	+
Fatty acid composition[c]	S, U[d]	S, U, T	S, U, T	S, U, T	S, U, T	S, U, T	S, U, T	S, U, T	S, U, T	S, U	S, U	S, U, T	S, U, T

DNA G+C content (mol%)	51–67	66–73	63–69	64.7	57–73	63–72	63–73	68–72	67.5	63.7	69.3–71.6	68–78	64–65

[a]The wall chemotype of *Segniliparus* has yet to be established.

[b]Symbols: +, positive; –, negative; and nd, not determined. Data taken from Butler et al., (2005); Soddell et al., (2006); and Adachi et al. (2007).

[c]Abbreviations: S, straight chain; U, unsaturated; T, tuberculostearic acid (10-methyloctadecanoic acid).

[d]*Corynebacterium bovis*, *Corynebacterium minutissimum*, *Corynebacterium urealyticum* and *Corynebacterium variabile* contain tuberculostearic acid (Kämpfer et al., 1999; Lechevalier et al., 1977).

[e]Examples of abbreviations: MK-9(H_2), menaquinone with two of the nine isoprene units hydrogenated; SQA and SQB, smaradiquinones A and B.

[f]Number of mycolic acid spots produced from whole organism methanolysates (Minnikin et al., 1975, 1980). In mycobacterial mycolic acids, double bonds may be converted to cyclopropane rings; methyl branches and other oxygen functions may be present (Dobson et al., 1985).

[g]Present in *Corynebacterium bovis* and *Corynebacterium urealyticum* (Kämpfer et al., 1999).

TABLE 30. Characteristics of the mycolic acid-less type strains of type species of wall chemotype IV genera classified in the order *Corynebacteriales*[a,b]

Characteristic	*Amycolicococcus*	*Hoyosella*	*Turicella*
Micromorphology	Cocci	Cocci found singly, in pairs, or in small groups	Single cells, V-shaped, or in palisades
Aerial hyphae	Absent	Absent	Absent
Major polar lipids[c]	DPG, PC, PE, PG, PI, GluNu	DPG, PE, PG, PI	nd
Muramic acid moieties	Acetylated	Acetylated	Acetylated
Predominant menaquinones	MK-7, 8	MK-8	MK-10, 11
Presence of tuberculostearic acid	+	+	+
DNA G+C content (mol%)	66.0	49.3	65–72

[a] Symbols: +, present; nd, not determined.

[b] Data taken from Funke et al. (1994), Jurado et al. (2009), and Wang et al. (2010).

[c] Abbreviations: DPG, diphosphatidylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol and GluNu, unknown glucosamine containing phospholipid.

Mycolic acids show structural variations which range from relatively simple mixtures of saturated and unsaturated components in corynebacteria to the highly complex mixtures characteristic of mycobacteria (Goodfellow and Magee, 1998; Minnikin, 1982, 1993; Minnikin and Goodfellow, 1980). Mycobacterial mycolates have 60–90 carbon atoms with up to 4 double bonds; those of the remaining genera vary in chain length and the number of double bonds (Table 30). Qualitative TLC analyses of mycolic acids after Minnikin et al. (1975) show that the methanolysates of mycobacteria, with the exception of *Mycobacterium brumae*, *Mycobacterium fallax*, and *Mycobacterium triviate* (Dobson et al., 1985; Luquin et al., 1993), give a multispot pattern, tsukamurellae two spots, and most of the remaining taxa a single spot (Table 29); the different Rf values of the mycolic acid spots reflect differences in chain lengths and structures (Embley and Wait, 1994; Minnikin, 1988, 1993; Minnikin et al., 1980; Yassin et al., 1997). *Segniliparus* strains also produce a multispot pattern (Butler et al., 2005). Mycolic esters can be positively identified on thin-layer chromatograms by their characteristic immobility when plates are subsequently washed in methanol water (5:2, v/v) (Minnikin et al., 1975). Mycobacterial species can be assigned to one of several groups based on the presence or absence of different types of mycolic acids (Goodfellow and Magee, 1998; Minnikin, 1988, 1993; Minnikin et al., 1984a, 1984c, 1985); the latter can be detected more precisely by two dimensional TLC using appropriate protocols (Dobson et al., 1985; Embley and Wait, 1994; Minnikin, 1988; Minnikin et al., 1980).

Several precipitation methods have been recommended to distinguish between mycobacterial mycolic acids and those from related taxa. Mycobacterial mycolic acids can be precipitated from ether solution by the addition of an equal (Kanetsuna and Bartoli, 1972) or double volume (Hecht and Causey, 1976) of ethanol. In contrast, mycolic acids from corynebacteria, gordoniae, and rhodococci are not precipitated in these procedures though Hecht and Causey (1976) detected their presence in supernatants by TLC. A more sensitive and reliable precipitation procedure was introduced by Hamid et al. (1993) to separate mycobacteria from other mycolic acid-containing genera. This method is based on the solubility of mycolic acid methyl esters in acetonitrile/toluene (1:2, v/v) and the insolubility of those from mycobacteria in acetonitrile/toluene (3:2, v/v).

Once the presence of mycolic acids has been detected, their esters can be extracted and studied further to yield additional taxonomic data, notably on the overall size of mycolic acids, their degree of unsaturation, and the length of alkyl side chains (Table 29). Methods used for such purposes include pyrolysis gas chromatography (Collins et al., 1982b; Kroppenstedt, 1985), mass spectrometry (Collins et al., 1982a), gas chromatography-mass spectrometry of trimethylsilyl ether and tetrabutyldimethyl derivatives of mycolic acids (Athalye et al., 1984; Pommier and Michel, 1985; Tomiyasu et al., 1981; Yano et al., 1978), and high performance liquid chromatography (HPLC) of *para*-bromophenyl and *N*-methyl-*N*-nitro-*p*-toluenesulfonamide derivatives of mycolic acids (Butler et al., 2005; Butler et al., 1996; Lévy-Trébault et al., 1986). Reverse-phase HPLC of *para*-bromophenyl esters of mycolic-acids provides a particularly rapid way of distinguishing between mycolic acid-containing genera (Butler et al., 1986); appropriate columns, detectors, and solvent gradients have been described by Butler and his colleagues (Butler et al., 1986, 1987; Butler and Kilburn, 1988; De Briel et al., 1992). In addition, different classes of mycobacterial mycolic acids can be separated by HPLC (Butler et al., 2005; Kaneda et al., 1995; Ramos, 1994; Steck et al., 1978). This separation is based upon chain lengths, the degree of unsaturation, and other functional groups in mycolic acids (Svensson et al., 1982).

10-Methyloctadecanoic (tuberculostearic) acid, phosphatidylethanolamine, and the acyl types of muramyl residues in wall peptidoglycans are important markers in the classification and identification of genera which belong to the order *Corynebacteriales* (Table 29 and Table 30). In addition, phosphatidylethanolamine has not been detected in some *Dietzia* species (Li et al., 2008). The genus *Corynebacterium* stands apart from other mycolic acid-containing genera as nearly all of its constituent species lack both phosphatidylethanolamine and tuberculostearic acid, though *Millisia*, *Smaragdicoccus*, and *Tomitella* strains do not contain this latter component. The genera *Corynebacterium* and *Dietzia* can be distinguished from the other mycolic acid-containing genera as they contain *N*-acetyl, as opposed to *N*-glycolyl residues in the glycan moiety of the peptidoglycan. The genera *Amycolicococcus*, *Hoyosella*, and *Tomitella* contain tuberculostearic acid and *N*-acetylated muramic acid residues, though differences are seen in the polar lipid patterns of the

former two taxa. Standard procedures are available for the detection of tuberculostearic acid (Kroppenstedt, 1985), phosphatidylethanolamine (Minnikin et al., 1984a), and the acyl residues of wall peptidoglycans (Uchida et al., 1999). A small-scale integrated procedure can be used for the detection of wall and lipid markers (O'Donnell et al., 1985).

Most of the genera assigned to the order *Corynebacteriales* can be separated solely on the basis of their predominant menaquinones (Table 29 and Table 30). The presence of fully unsaturated menaquinones with nine isoprene units (MK-9) serves to distinguish tsukamurellae from all other mycolic acid-containing genera (Collins et al., 1988b; Nam et al., 2004) and from the unsaturated menaquinones characteristic of the genera *Amycolicoccus*, *Hoyosella*, and *Turicella* (Funke et al., 1994; Jurado et al., 2009; Wang et al., 2010). Nocardiae and skermaniae can be distinguished from all of the other taxa as they contain predominant proportions of hexahydrogenated menaquinones with eight isoprene units where the last two are cyclized (Blackall et al., 1989; Chun et al., 1997; Collins et al., 1987; Howarth et al., 1986). In turn, smaragdicocci contain two novel cyclic forms of menaquinones, smaragdiquinone A-8 (H_4, ω-cycl) and smaragdiquinone B-8 (H_4, ω-cycl) (Adachi et al., 2007). Corynebacteria, dietziae, millisiae, and rhodococci all contain major amounts of dihydrogenated menaquinones with eight isoprene units as the predominant components; gordoniae, mycobacteria, and williamsiae have major proportions of the corresponding component with nine isoprene units (Collins et al., 1977, 1985; Goodfellow and Maldonado, 2006). Detailed analytical procedures for establishing menaquinone profiles have been described (Collins, 1994; Kroppenstedt, 1982, 1985), including the integrated method introduced for the analysis of bacterial quinones and polar lipids (Minnikin et al., 1984a).

Co.ry.ne.bac.te.ri.a.ce′a.e. N.L. neut. n. *Corynebacterium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Corynebacteriaceae* the *Corynebacterium* family.

The pattern of 16S rRNA signatures consists of nucleotides at positions 250 (U), 316:337 (U–G), 418:425 (C–G), 586:755 (U–G), 599:639 (C–G), 662:743 (U–G), 987:1218 (G–C), and 1059:1198 (U–A). **The peptidoglycan type is A1γ with directly cross-linked *meso*-diaminopimelic acid. The cell wall contains arabinogalactan**. The muramic acid type is acetyl. **Major fatty acids are $C_{16:0}$, $C_{18:1}$ ω9*c***; tuberculostearic acid (10-methyl $C_{18:0}$) may be present. **The quinone system consists exclusively of menaquinones**; most strains contain major amounts of **menaquinones with either eight or nine isoprenoic units in the side chain, one of which is saturated [MK-8(H_2), MK-9(H_2) or a mixture of both]**, but completely unsaturated menaquinones are found in *Turicella otitidis*. Most *Corynebacterium* species contain **mycolic acids with 22–38 carbons, but some species lack** mycolic acids, as does *Turicella otitidis*.

The family contains the type genus *Corynebacterium* and the genus *Turicella*.

DNA G+C content (mol%): 46–74.

Type genus: **Corynebacterium** Lehmann and Neumann 1896, 350[AL] emend. Bernard, Wiebe, Burdz, Reimer, Ng, Singh, Schindle and Pacheco 2010, 877.

Further descriptive information

The family *Corynebacteriaceae* is composed of the genera *Corynebacterium* with more than 80 species and the monospecific genus *Turicella*. These taxa form a clade which is clearly separated from related families classified in the order *Corynebacteriales*. 16S rRNA gene sequence similarities between some *Corynebacterium* species are down to <92%, whereas *Turicella otitidis* shares similarity values higher than 92% with several *Corynebacterium* species. Phylogenetic calculations based on 16S rRNA gene sequences (Brennan et al., 2001; Collins et al., 1998; Ludwig et al., 2009b; Pascual Ramos et al., 1997; Ruimy et al., 1995) place *Turicella otitidis* within the radiation of *Corynebacterium* species and not as a separated line of descent within the family.

Most *Corynebacterium* species contain mycolic acids, though *Corynebacterium amycolatum*, *Corynebacterium atypicum*, *Corynebacterium caspium*, *Corynebacterium ciconiae*, *Corynebacterium kroppenstedtii*, and *Turicella otitidis* lack this component (Collins et al., 1988a, 1998, 2004; Fernández-Garayzábal et al., 2004; Funke et al., 1994; Hall et al., 2003). The length of the mycolic acids found in strains varies between 22 and 38 carbons, but usually only one or two mycolic acid species predominate (Collins et al., 1982b). *Corynebacterium bovis* contains major amounts of a mycolic acid composed of 28 carbons with a single double bond, though two members of the species exhibit a major mycolic acid with 24 carbons with a single double bond; in *Corynebacterium diphtheriae* the major mycolic acid contains either 32, 34, or 36 carbons each with two double bonds or 32 carbons with a single double bond and a second major compound consisting of 34 carbons with two double bonds. Mycolic acids with 34 carbons with one double bond have been found in *Corynebacterium callunae*, *Corynebacterium glutamicum*, *Corynebacterium minutissimum*, and *Corynebacterium mycetoides*; *Corynebacterium pseudodiphtheriticum* strains show a major, completely unsaturated mycolic acid with 32 carbons and 34 carbons with one double bond. Strains of *Corynebacterium pseudotuberculosis* contain major amounts of mycolic acids with either 32 or 36 carbons with one or two double bonds, 34 and 36 carbons each with one double bond, 32 and 36 carbons with the smaller mono-unsaturated and the larger di-unsaturated or two mycolic acid species with 32 carbons with one completely saturated and the other mono-unsaturated.

Like other members of the order *Corynebacteriales*, the fatty acid composition of representatives of the family *Corynebacteriaceae* is mainly composed of saturated and unsaturated, unbranched acids with $C_{16:0}$ and $C_{18:1}$ ω9*c* predominating, though some species also contain tuberculostearic acid (10-methyl-$C_{18:0}$), including *Corynebacterium ammoniagenes* (Collins et al., 1982a), *Corynebacterium bovis* (Collins et al., 1998), *Corynebacterium cystitidis*, *Corynebacterium minutissimum*, and *Corynebacterium pilosum* (Herrera-Alcaraz et al., 1990), *Corynebacterium kroppenstedtii* (Collins et al., 1998), *Corynebacterium terpenotabidum* (Takeuchi et al., 1999), *Corynebacterium urealyticum* (Pitcher et al., 1992), and *Corynebacterium variabilis* (Collins, 1987a; Collins et al., 1982b). The peptidoglycan is of A1γ type with the characteristic diamino acid diaminopimelic acid.

Quinone systems reported for *Corynebacterium* species are MK-8(H_2), MK-9(H_2), or a mixture of both (Bernard et al., 2010; Collins, 1987b; Collins et al., 1979, 2001b; Collins and Jones, 1983b; Fudou et al., 2002; Pitcher et al., 1992; Takeuchi et al., 1999; Zimmermann et al., 1998); significant amounts of MK-7(H_2) may also be present (Kämpfer et al., 2009). In contrast, *Turicella otitidis* contains completely unsaturated menaquinones (MK-10, MK-11). Some significant variability in the G+C content of genomic DNA of *Corynebacterium* species has been reported. The lowest value was determined for *Corynebacterium kutscheri* (46 mol%) and the highest for *Corynebacterium auris* (74 mol%).

Taxonomic comments

The family *Corynebacteriaceae* contains the type genus *Corynebacterium* and the monospecific genus *Turicella*. The status of *Turicella* as a genus is supported by phenotypic characteristics (completely unsaturated menaquinones MK-10 and MK-11, lack of mycolic acids). In contrast, 16S rRNA gene sequence data, G+C content, and heterogeneity in several chemotaxonomic characteristics that are considered to be useful for defining genera suggest that the status of the genus *Corynebacterium* and affiliated species needs to be revisited.

A strong case can be made for assigning *Corynebacterium* species to several genera based on 16S rRNA gene sequence similarities. The intra-generic 16S rRNA gene similarities of most prokaryotic genera are at or above 95%, whereas the lowest sequence similarities among *Corynebacterium* species are between 91–92%. The G+C content of genomic DNA within

genera is rarely more than 10 mol% (Goodfellow et al., 1997). In contrast, the DNA base composition of the genus *Corynebacterium* varies between 46 (*Corynebacterium kutscheri*; Pitcher, 1983) and 74 mol% (*Corynebacterium auris*; Funke et al., 1995c). Other chemical markers which might be useful in the assignment of *Corynebacterium* species to novel genera include menaquinone composition and the presence/absence of mycolic acids. However, the task of unraveling the structure of the genus *Corynebacterium* is a daunting one, as the descriptions of many of the constituent species lack information on key chemical markers.

Genus I. **Corynebacterium** Lehmann and Neumann 1896, 350[AL] emend. Bernard, Wiebe, Burdz, Reimer, Ng, Singh, Schindle and Pacheco 2010, 877

KATHRYN A. BERNARD AND GUIDO FUNKE

Co.ry.ne.bac.te′ri.um. Gr. n. *coryne* a club; L. neut. n. *bacterium* a rod, and in biology a bacterium (so called because the first ones observed were rod-shaped); N.L. neut. n. *Corynebacterium* a club bacterium.

Straight to slightly curved rods with tapered ends. Rods are usually short or of medium length. Club-shaped forms may be observed; sometimes ellipsoidal, ovoid or rarely, "whip handles" (see below, *Corynebacterium matruchotii*) or thinner rods with bulges (see below, *Corynebacterium sundsvallense*) observed. **Snapping division produces angular and palisade arrangements of cells. Gram-stain-positive; some cells stain unevenly**. Metachromatic (synonym being polyphosphate) granules may be observed for some species. Not-acid-fast (Ziehl–Neelsen stain), and no species has aerial mycelium. Nonsporeforming. **All species are nonmotile**. **All species are catalase positive**. All species are oxidase negative except for *Corynebacterium bovis*, *Corynebacterium aurimucosum*, *Corynebacterium doosanense*, and *Corynebacterium maris* (below). **Many species are facultatively anaerobic and some are aerobic**. Chemoorganotrophs. Some species are lipophilic. Many species produce acid from glucose and some other sugars in peptone media. Several species alkalinize citrate as sole carbon sources, but most do not.

Cell-wall peptidoglycan is based on *meso*-diaminopimelic acid (*meso*-DAP) (variation of A1γ of Schleifer and Kandler). Glycan type of cell walls contains acetyl residues. **Major cell-wall sugars are arabinose and galactose** (also referred to as arabinogalactan), but occasionally other sugars detected. **Short-chain mycolic acids** (also referred to as corynomycolates, corynemycolates, or α-alkyl-β-hydroxy-long-chain fatty acids) **22–36 carbons in length may be present**, but some species lack mycolates entirely (see below, *Corynebacterium amycolatum*, *Corynebacterium atypicum*, *Corynebacterium caspium*, *Corynebacterium ciconiae*, and *Corynebacterium kroppenstedtii*). Long-chained cellular fatty acids are of the straight-chain saturated and monounsaturated types, with significant amounts of hexadecanoic (palmitic, $C_{16:0}$), octadecanoic ($C_{18:0}$), and *cis*-9-octadecenoic ("oleic", $C_{18:1}$ ω9*c*) acids as major components. Small or moderate amounts of tuberculostearic acid (TBSA) (10-methyl $C_{18:0}$) and other cellular fatty acids may also be present. *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, *Corynebacterium pseudotuberculosis*, and *Corynebacterium vitaeruminis* are the only species where significant amounts of the 16:1 isomer, $C_{16:1}$ ω7*c*, are observed and corynemycolates may be observed to coelute with cellular fatty acids (Bernard et al., 1991). Branched-chain or hydroxylated fatty acids are absent or found only in trace amounts. Metabolic products of fermentation may include small volumes of acetic, succinic, and lactic acids, but production of propionic acid is species specific (Bernard et al., 2002). Dihydrogenated menaquinones with either **eight [MK-8(H_2)] and/or nine [MK-9(H_2)] isoprene units** are present. In addition, MK-7(H_2) has been detected for *Corynebacterium glaucum* and *Corynebacterium lubricantis*; small amounts of MK-10(H_2) have also been found for *Corynebacterium thomssenii* (below). Phospholipids include simple, phosphatidylinositol, phosphatidylinositol dimannoside(s), phosphatidylglycerol trehalose dimycolates, and other glycolipids (Collins and Cummins, 1986; Yague et al., 1997). Phosphatidyethanolamine is absent except for *Corynebacterium bovis* and *Corynebacterium urealyticum* (Kämpfer et al., 1999).

DNA G+C content (mol%): 46–74.

Type species: **Corynebacterium diphtheriae** (Kruse 1886) Lehmann and Neumann 1896, 350 ("*Bacillus diphtheria*" Kruse *in* Flügge1886, 225).

Further descriptive information

The genus *Corynebacterium* contains 84 validly published named species at the time of writing (May 2010). Phylogenetic relatedness among *Corynebacterium* species was first inferred by nearly full 16S rRNA gene sequence relationship studies in 1995 (Pascual et al., 1995; Ruimy et al., 1995) (Figure 83). Since the 1st edition of the *Manual*, members of this genus have been restricted to species most closely related by 16S rRNA gene sequencing to the type species, *Corynebacterium diphtheriae.* The genus *Corynebacterium* and the closely related genus, *Turicella*, are sole genera in the family *Corynebacteriaceae* (Ludwig et al., 2009a; Zhi et al., 2009). In addition to a close relationship by 16S rRNA or *rpoB* gene sequence analyses (described below), *Corynebacterium* species share phenotypic, chemotaxonomic, and other commonalities, and so taxa from the 1st edition of this *Manual* which do not fit this description have now been reassigned to other genera and families (outlined below). The degree of variance using 16S rRNA gene sequencing is 2% or greater for many species in this genus, and so most are discernable from each other without study of additional gene targets if comparison of nearly full (~1400–1500 bp) sequence of the 16S rRNA gene is used (Stackebrandt and Ebers, 2006). Shorter, but more rapidly analyzed lengths (400–500 bp) of 16S rRNA gene sequence have been used for characterization of *Corynebacterium* species for rapid identification (Tang et al., 2000). However, when full sequencing data for the 16S rRNA gene for all taxa are analyzed, some species are related with a degree of variance which is ≤2%. These include: *Corynebacterium afermentans*, *Corynebacterium coyleae*, *Corynebacterium mucifaciens* (<2%); *Corynebacterium aurimucosum*, *Corynebacterium minutissimum*, and *Corynebacterium singulare* (<2%); *Corynebacterium sundsvallense*

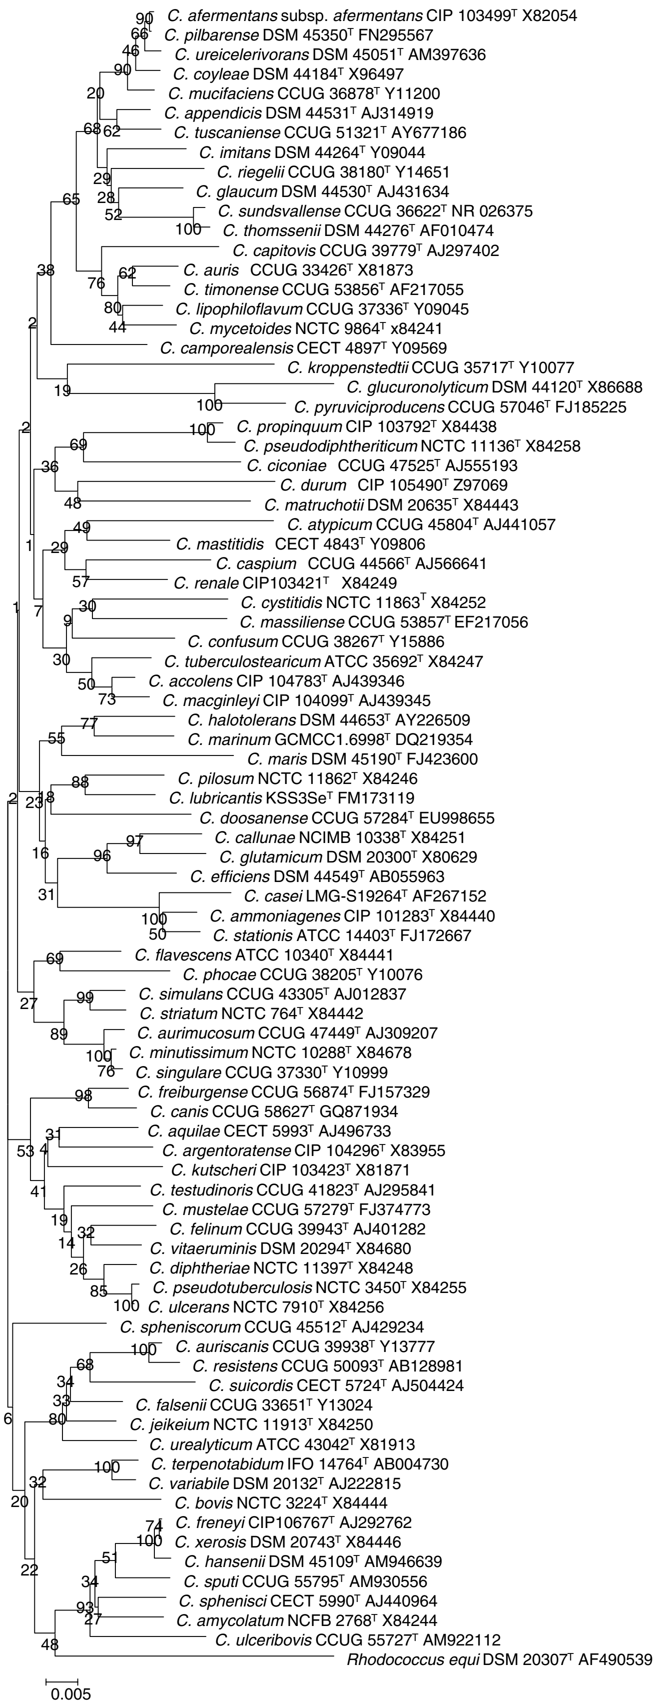

FIGURE 83. Phylogenetic tree of 16S rRNA gene sequences using type strains of *Corynebacterium* species, with *Rhodococcus equi* as outlier. Bar represents % substitutions. Alignment was done using CLUSTAL W

and *Corynebacterium thomssenii* (<1.5%); *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis* (<1% to each other, both <2% to *Corynebacterium diphtheriae*); *Corynebacterium propinquum* and *Corynebacterium pseudodiphtheriticum* (<2%); *Corynebacterium xerosis*, *Corynebacterium freneyi*, and *Corynebacterium hansenii* (<2%); and *Corynebacterium macginleyi* and *Corynebacterium accolens* (<2%).

Corynebacterium species which cannot be discerned by 16S rRNA gene sequencing can be further characterized by sequencing of other gene targets. One widely used method is that of *rpoB* gene sequencing, as an adjunct to or in lieu of, 16S rRNA gene sequencing. When full or partial *rpoB* gene sequences were used, taxa with ≥95% identity are thought to be members of the same species and those with ≥ 98% identity were deemed to be members of the same subspecies (Khamis et al., 2004, 2005). *Corynebacterium xerosis*, *Corynebacterium freneyi*, and *Corynebacterium hansenii*, which could not be discerned using 16S rRNA, 16S–23S spacer region or *rpoB* gene sequencing, were determined only by DNA–DNA hybridization to be separate species (Renaud et al., 2007). Restriction length polymorphism using *cfo*I fragment of the 16S–23S region has been used to characterize *Corynebacterium freneyi* strains (Funke and Frodl, 2008b). Sequencing of a gene associated with cell division, *div*IVA, has been applied to discern *Corynebacterium amycolatum* from closely related species (Letek et al., 2006). A PCR-based assay to detect *dtxR*, a chromosomal iron-dependent repressor gene associated with *Corynebacterium diphtheriae* strains, has been used as a method to screen for these organisms (Pimenta et al., 2008). A number of other approaches have been used to try to separate closely related *Corynebacterium* species. Amplified rRNA-restriction analysis (ARDRA) using the enzymes *alu*I, *cfo*I, and *rsa*I was applied as a means to differentiate among otherwise closely related species (Vaneechoutte et al., 1995). Length polymorphisms of the16S–23S rRNA gene spacer region were used to reveal unexpected heterogeneity among strains of species otherwise thought to be monophyletic (Aubel et al., 1997). Ribotyping and RFLP (restriction fragment length polymorphisms) have been used to differentiate species using various enzymes (Björkroth et al., 1999). Entire genome studies of *Corynebacterium* species have been completed to date for *Corynebacterium glutamicum* (ATCC 13032^{T}) (Kalinowski et al., 2003), *Corynebacterium efficiens* (YS-314^{T}) (Nishio et al., 2003), *Corynebacterium diphtheriae* (NCTC 13129) (Cerdeno-Tarraga et al., 2003), *Corynebacterium jeikeium* (strain K411) (Tauch et al.,

FIGURE 83. (continued) software with MEGA 4 software (Kumar et al., 2008). Numbers represent neighbor joining (NJ) distances, with robustness estimated after 1000 bootstraps. Sequence from strains found in collections cited on the World Federation of Culture Collections website (www.wfcc.info) were used. ATCC, American Type Culture Collection, Manassas, VA, USA; CCUG, Culture Collection, University of Goteborg, Goteborg, Sweden; CECT, Coleccion Espanola de Cultivos Tipo, Valencia, Spain; CIP, Collection Institut Pasteur, Paris, France; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany; LMG, Laboratorium voor Microbiologie, Universiteit Gent (part of the) Belgian Coordinated Collections of Microorganisms, Gent, Belgium; NBRC, National Institute of Technology and Evaluation (NITE) Biological Resource Center, Chiba, Japan. NCIMB, National Collections of Industrial Food and Marine Bacteria (incorporating the NCFB), Aberdeen Scotland and NCTC, National Collection of Type Cultures, London UK, both are part of the United Kingdom National Culture Collection (UKNCC).

2005), *Corynebacterium urealyticum* (DSM 7109^T) (Tauch et al., 2008b), *Corynebacterium kroppenstedtii* (DSM 44385^T) (Tauch et al., 2008a), and a black-pigmented *Corynebacterium aurimucosum* strain (CN-1) (Trost et al., 2010). These range in size from *Corynebacterium urealyticum* (2,369,217 bp) to *Corynebacterium glutamicum* (3,309,401 bp), with a number of additional projects involving *Corynebacterium* species under way as of this writing. Although still in its infancy, comparative analysis of these entire genomes has provided insight into common or different protein expressions found among these taxa including a set of conserved, DNA-binding transcriptional regulators consisting of 28 proteins that is involved with the regulation of cell division, septation, SOS and stress response, carbohydrate metabolism, and macroelement and metal homeostasis (Brune et al., 2005).

Corynebacterium species epidemiologically linked in an outbreak have been characterized comprehensively using several molecular typing schemes. Concerted efforts to track a large diphtheria outbreak in former Soviet Union (FSU) states, spearheaded by the European laboratory working group on diphtheria (DIPNET), have been studied by various methods, particularly rRNA gene restriction pattern determination (ribotyping). Multilocus enzyme electrophoresis (MEE), yielding an electromorph (ET) type, pulsed field gel electrophoresis (PFGE), randomly amplified polymorphic DNA (RAPD), and amplified fragment length polymorphism (AFLP) analyses have been used to characterize outbreak strains (De Zoysa et al., 1995b; Popovic et al., 1996) and isolates which predated the outbreak from those geographic areas (Skogen et al., 2002). By these means, a clonal group of closely related strains, particularly ribotypes Sankt-Peterburg, Rossija and others, were found to be largely responsible for the Russian and FSU state countries outbreak. With this information, movement of clonal strains to other countries could be tracked (Mokrousov et al., 2005). Four molecular methods (ribotyping, AFLP, PFGE, and RAPD) for typing *Corynebacterium diphtheriae* strains have been compared. Ribotyping was found to provide the most useful and discriminatory information (De Zoysa et al., 2008) and used to propose international nomenclature rules (Grimont et al., 2004). A multi-method approach was used to characterize a large number of American and Canadian isolates; clonal groups distinct from European outbreak strains and in circulation for many years, in spite of universal vaccination programs in both countries, were found to persist (Marston et al., 2001). Further discrimination among strains recovered during the Russian/FSU state outbreak have been studied using a microarray approach, the use of which could arguably eliminate inherent laboratory inter-reproducibility issues or cumbersome methods particularly associated with PFGE, MEE, and ribotyping (Mokrousov et al., 2009). A multilocus, sequence typing (MLST) scheme has been described for *Corynebacterium diphtheriae* surveillance and data derived from sequencing seven housekeeping genes (*atpA*, *dnaE*, *dnaK*, *fusA*, *leuA*, *odhA*, *rpoB*) were curated, compared to a database, assigned a sequence type, and interpreted (Bolt et al., 2010; Dallman et al., 2008).

Molecular typing methods for *Corynebacterium* species other than *Corynebacterium diphtheriae* have been occasionally described. Thirty-two strains of *Corynebacterium urealyticum* from humans or animals, recovered over several years, were extensively characterized by ribotyping. There, most human isolates were generally found to be multidrug-resistant (MDR) and clustered into ribotypes called 8, 9, and 10, in contrast with animal strains which were assigned to ribotypes 5 and 6 and were more susceptible to antibiotics (Nieto et al., 2000). A unique strain of *Corynebacterium striatum* which produced a diffusible brown pigment and was associated with respiratory, wound, or blood infections in an intensive care unit (ICU) was found to be clonal, when studied by DNA restriction fragment patterns and Southern hybridization with an *att* site probe, whereas apigmented, contemporary strains to the outbreak had diverse genetic patterns (Leonard et al., 1994). RAPD method was used to study an outbreak among patients in a surgical ICU, where a genetically and biochemically identical clone with identical antibiogram, had spread from patient to patient and could be discerned from other strains circulating in the ward over a 1 year period (Brandenburg et al., 1996). Ribotyping and RAPD were used to prove that cutaneous sites and blood culture isolates of *Corynebacterium striatum* from the same patient were identical (Martin et al., 2003). PFGE was used to evaluate 36 MDR *Corynebacterium striatum* strains recovered primarily from ventilatory-related respiratory or central venous catheter infections from three hospitals over a 2-year period, where infection was associated with a single clone possessing *ermX*, *tet A/B*, *cmx A/B*, and *aphA1* resistance genes (Campanile et al., 2009). PFGE was used to type 48 *Corynebacterium striatum* strains recovered from patients in a community hospital over a 5-year period, primarily from respiratory specimens; these could be assigned into 14 patterns with 20 subtypes and provide definitive linkages for nosocomial acquisition (Otsuka et al., 2006). Strains of *Corynebacterium ulcerans* recovered from a patient and her dog were found to be identical but differed from reference strains when characterized by ribotyping (Lartigue et al., 2005). Ribotyping was also used to link infection by a toxigenic strain of *Corynebacterium ulcerans* with a patient and companion animals (two dogs, one cat) (Hogg et al., 2009). An outbreak of fluoroquinolone-resistant *Corynebacterium macginleyii* was studied by MLST of seven housekeeping genes (*adk*, *dnaA*, *fumC*, *gltA*, *gyrB*, *icd*, and *purA*) in parallel to RAPD analysis, with the two methods being found to be equally discriminating (Eguchi et al., 2008). *Corynebacterium pseudotuberculosis* outbreaks in sheep and goats have been studied using PFGE (Connor et al., 2007).

Metabolic pathways and metabolism. *Corynebacterium* species historically have been characterized as having metabolisms which are fermentative, oxidative, or neither fermentative or oxidative (von Graevenitz and Bernard, 2003). Three closely related species, *Corynebacterium glutamicum*, *Corynebacterium callunae*, and *Corynebacterium efficiens*, have had very extensive metabolic, chemotaxonomic, and genetic properties studied because of their usefulness in biotechnological production of amino acids (Bayan et al., 2003; Wendisch et al., 2006). Comprehensive metabolic pathways and putative functions have been conjectured for species where complete genome studies have been done (Brune et al., 2005; Cerdeno-Tarraga et al., 2003; Kalinowski et al., 2003; Mokrousov, 2009; Nishio et al., 2003; Nishio et al., 2004; Tauch et al., 2008a, 2008b; Wendisch et al., 2006).

Pathogenicity, ecology, miscellaneous. *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, and *Corynebacterium. pseudotuberculosis* are the only species which may produce diphtheria toxin (DT), a potent exotoxin which plays a significant role in pathogenicity. The resultant disease, diphtheria, has histori-

cally been associated with significant morbidity and mortality in humans and animals, prior to universal use of an efficacious vaccine in countries around the world with higher socio-economic means (Funke et al., 1997f). In diphtheria, DT contributes to the formation of a pseudomembrane in the nasopharynx of the patient; although the organism is rarely found outside the infected area, the toxin, once absorbed by the circulatory system, can cause systemic complications, such as myocarditis and neuritis. Therefore, early administration of diphtheria antitoxin (DAT), a commercial immunoglobulin which neutralizes circulating DT, is critical for patient care, but local stockpiles of DAT may not exist or be in limited supply in countries where diphtheria has low prevalence (Wagner et al., 2009). Diphtheria is still endemic in some subtropical and tropical countries as well as among individuals of certain ethnic groups (e.g. indigenous peoples in the Americas and Australia). At population level, endemic geographically-specific variants of *Corynebacterium diphtheriae* are influenced by human host factors, public health control efforts (i.e. universal vaccination), and socio-economic conditions. Importation of (toxigenic) strains, or lysogenization by a bacteriophage (also called corynephage) of local strains, may instigate an outbreak (Mokrousov, 2009).

It has been known since the 1950s that nontoxigenic strains of *Corynebacterium diphtheriae* could become toxigenic after infection by temperate bacteriophages and a one-to-one correlation exists between the presence of the *tox* gene mechanism on a bacteriophage and subsequent DT production. The biology, structure, and molecular epidemiology of DT and the *tox* gene have been comprehensively reviewed (Holmes, 2000; Yates et al., 2006). Fragment A of the *tox* gene contains ADP-ribosyltransferase activity; fragment B contains the receptor-binding and membrane-associating domains, with the structural *tox* gene being under the control of the chromosomal iron-dependant repressor, *dtxR*, and a promoter-operator region (Nakao et al., 1996).

Most nontoxigenic strains of *Corynebacterium diphtheriae* and most *tox* gene-negative bacteriophages do not contain detectable *tox*-related DNA sequences (Holmes, 2000). However, some strains contain detectable *tox* genes but do not express DT. It has been suggested that these strains have one or more of a variety dysfunctional genetic mechanisms which preclude DT production (von Graevenitz and Bernard, 2003); such isolates are considered as non-toxigenic with respect to public health response (Efstratiou et al., 1998; Efstratiou and George, 1999). The *dtxR* gene has been demonstrated to be heterogeneous, but all subtypes of this gene, if functional in strains lyosogenized by corynephage, could theoretically produce DT, and the possibility exists that non-toxigenic strains could revert to toxigenic status (De Zoysa et al., 2005).

Corynephage insert into the *Corynebacterium diphtheriae* chromosome at either one of two specific attachment sites, *attB1* and *attB2* (Oram et al., 2007; Seto et al., 2008). Protein transcribed by the DT repressor gene (*dtxR*), serves as a global repressor of metabolism in *Corynebacterium diphtheriae*. Cellular functions which are negatively regulated by iron (Fe^{2+}) levels include production of DT, synthesis of a siderophore (also called corynebactin), corynebactin-dependant iron uptake, and utilization of iron from heme (Qian et al., 2002). DT catalyzes the NAD-dependant ADP ribosylation of elongation factor 2 and inhibits protein synthesis and death in cells from humans or susceptible animals (Qian et al., 2002).

Diphtheria-like disease in humans as manifested by *Corynebacterium ulcerans*, although long understudied, is now being described as an emerging, possibly zoonotic disease (Bonmarin et al., 2009; Hogg et al., 2009). Different opinions exist on the efficacy of diphtheria toxoid vaccine to protect against the effects of infection by toxigenic *Corynebacterium ulcerans* (Schuhegger et al., 2008a, 2008b). Differences (up to ~5%) exist between nucleotide and amino acid sequences of *Corynebacterium diphtheriae* and *Corynebacterium ulcerans tox* genes (Sing et al., 2003); therefore, further study is required to clarify the efficacy of diphtheria toxoid to protect against disease caused by *Corynebacterium ulcerans*. Features of the attachment site in *Corynebacterium ulcerans* have been reviewed (Seto et al., 2008).

Complete genome analysis of a strain of *Corynebacterium jeikeium*, an opportunistic pathogen which is usually MDR and always lipophilic, revealed a 14,323-bp bacteriocin-producing plasmid which is designated pKW4. This analysis revealed that "lipophila" in *Corynebacterium jeikeium*, but probably in all other lipophilic species described in this section, is expression of a fatty acid auxotrophy due to the absence of fatty acid synthase (Tauch et al., 2005). This phenomenon was also observed from complete genome analysis of the lipophile *Corynebacterium kroppenstedtii* which, as a species which lacks mycolates, was also found to lack a mycolate reductase gene (Tauch et al., 2008a).

The role of plasmids, as bearers of virulence factors or in association with increased pathogenicity among *Corynebacterium* species, is poorly understood. The complete genome of an unusual black-pigmented strain of *Corynebacterium aurimucosum* (ATCC 700975, designated the type strain of *Corynebacterium nigricans*, CN-1^T) that was associated with the female genital tract of a woman who experienced a spontaneous abortion during month 6 of her pregnancy, was described. A 29,037 bp plasmid designated pET44827 was found to code for a non-ribosomal peptide synthetase, which appeared to play a key role in the synthesis of the black pigment; this pigment was conjectured to play a role in both protecting the bacterium from the high hydrogen peroxide concentration of the vagina and play a role in causing complications in pregnancy (Trost et al., 2010).

Phospholipase D (Pld) is a major virulence factor of *Corynebacterium pseudotuberculosis*, the organism causing caseous lymphadenitis in sheep and goats in addition to being able to harbor corynephage and express DT. Pld is detected in *Corynebacterium ulcerans* as well as *Arcanobacterium hemolyticum*; in clinical microbiology laboratories, the presence of Pld is demonstrated by the inhibition of the Christie–Atkins–Munch–Petersen (CAMP) reaction (also called the reverse CAMP test) (Barksdale et al., 1981). Pld regulation and expression has been found to be a complex process which includes assisting with dissemination of the bacterium from site of infection to the lymph nodes and thereafter reducing macrophage viability (McKean et al., 2007). Rapid detection of *Corynebacterium pseudotuberculosis* among diseased animals has been made possible by the use of a multiplex assay to detect the 16S rRNA, *rpoB*, and *pld* genes of this bacterium (Pacheco et al., 2007).

Pathogenicity, virulence factors and ecological niches for other species remain understudied and largely unknown.

Antibiotic susceptibility and mechanisms of resistance. Antibiotic susceptibility of *Corynebacterium* species is less well studied compared with many other Gram-stain-positive rods because, for many years, "diphtheroids" were dismissed as contaminants and did not merit either the resources or interest required for further study. In addition, there was no consensus on standardized protocols and breakpoint interpretation for many years, so a wide variety of methods were independently used for clinically relevant isolates. Application of the broth microdilution method and specific MIC breakpoints were formally recommended by the CLSI in 2006 (Clinical Laboratory Standards Institute, 2006). However, Etest (e.g. Martinez-Martinez et al., 1995a), variations of agar dilution (e.g. Lagrou et al., 1998; Soriano et al., 1995), and disk diffusion (e.g. Riegel et al., 1996a; Weiss, et al., 1996) have also been used. A lack of precise species assignments and a lack of published historical data have made it difficult to compare older data to contemporary data to see if significant changes in resistance for specific taxa have occurred over time.

In 1971, *Corynebacterium diphtheriae* strains were found to be susceptible to commonly used drug classes tested, particularly those used for acute care treatment (penicillin and erythromycin) (McLaughlin et al., 1971). In 1995, diphtheria strains were found to be susceptible to beta lactams, third generation cephalosporins, vancomycin, pefloxacin, imipenam but not pefixime, azreonam, cefpodoxime, and some earlier generation cephalosporins; occasional strains were resistant to lincomycin and erythromycin (Patey et al., 1995). Antibiotic susceptibility patterns for species other than *Corynebacterium diphtheriae* confirmed observations that some or most strains of specific species, including *Corynebacterium amycolatum*, *Corynebacterium striatum*, *Corynebacterium minutissimum*, *Corynebacterium afermentans*, *Corynebacterium argentoratense*, *Corynebacterium auris*, *Corynebacterium glucuronolyticum*, lipophilic species *Corynebacterium jeikeium*, *Corynebacterium tuberculostearicum* (or as provisionally identified as CDC group G2), and *Corynebacterium urealyticum*, were often resistant to two or more drug classes (Funke et al., 1996b; Lagrou et al., 1998; Riegel et al., 1996a; Soriano et al., 1995; Williams et al., 1993). The new glycylcycline, tigecycline, and other commonly used antibiotics were evaluated against various *Corynebacterium* species, where tigecycline, as well as linezolid, daptomycin, vancomycin, and quinupristin/dalfopristin demonstrated good *in vitro* activity against isolates, but *Corynebacterium coyleae* and *Corynebacterium aurimucosum* strains were found to be MDR (Fernandez-Roblas et al., 2009). A daptomycin-resistant strain of *Corynebacterium jeikeium* has been reported (Schoen et al., 2009). *Corynebacterium resistens* was described as being susceptible only to vancomycin and minocycline but resistant to other drugs tested (Otsuka et al., 2005a).

In 1980, the presence of a 9.5 MDa plasmid was described as being associated with erythromycin resistance for strains of *Corynebacterium diphtheriae* (Schiller et al., 1980). In 1990, PCR was used to detect *erm* genes, i.e. genes encoding erythromycin ribosome methylases (rRNA methylases) that are linked to erythromycin resistance, from a variety of species (Arthur et al., 1990). Subsequently, studies of resistance mechanisms for various taxa have been reviewed including, among others, *mef* genes (macrolide efflux pump) and *erm* family genes, of which *ermB*, *ermC*, and particularly *ermX* have been detected among *Corynebacterium* species (Roberts, 2008). The *ermX* gene, believed to be borne on plasmids or transposons, adds one or two methyl groups to a single adenine in the 23S rRNA moiety and confers high level resistance to macrolides, lincosamides, and streptogramin B (MLS phenotype), as evidenced by resistance to at least erythromycin and clindamycin but often to other drug classes (Roberts, 2008). The *ermX* gene from *Corynebacterium jeikeium* has been linked to transposon Tn*5432* for some, but not all, isolates studied (Rosato et al., 2001). To date, resistance as linked to the presence of *ermX* has been reported in *Corynebacterium amycolatum* and *Corynebacterium jeikeium* (Rosato et al., 2001; Tauch et al., 2005; Yague Guirao et al., 2005), *Corynebacterium coyleae* (Fernandez-Natal et al., 2008), *Corynebacterium striatum* (Campanile et al., 2009; Otsuka et al., 2006), *Corynebacterium diphtheriae* (Tauch et al., 2003), and *Corynebacterium urealyticum* (Tauch et al., 2008b). The *ermX* gene was not detected among complete genome studies of *Corynebacterium kroppenstedtii* and a black pigmented *Corynebacterium aurimucosum* strain (Tauch et al., 2008b; Trost et al., 2010). Resistance to quinolones, due to a mutation in the *gyrA* gene, was found among clinical isolates of *Corynebacterium amycolatum* and *Corynebacterium striatum* (Sierra et al., 2005). A single amino acid substitution at position 83 of the *gyrA* gene generated a norfloxacin-resistance phenotype, but double mutation with amino acid substitutions at positions 83 and 87 gave rise to high level resistance to other fluoroquinolones in a study of *Corynebacterium macginleyi* isolates involved in ocular infections (Eguchi et al., 2008). *Corynebacterium striatum* strains were found to possess *ermX*, *tet A/B* (related resistance, tetracycline, oxytetracycline, and oxacillin), *cmx A/B* (related resistance chloramphenicol) and *aphA1* (related resistance, aminoglycoside) genes (Campanile et al., 2009). With time, other antibiotic resistance mechanisms among *Corynebacterium* species will be elucidated.

Ecology and habitat. There are at time of writing, ~51 medically relevant species have been described that cause occasional infections in humans or are transmitted to humans by zoonotic means. Most are deemed to be rare opportunistic pathogens. Some species thought to be part of the common skin flora, such as *Corynebacterium amycolatum*, *Corynebacterium jeikeium*, and some of the other lipophilic species, have been found to be resistant to multiple drug classes and can cause significant and occasionally fatal disease, particularly in immunocompromised patients or nosocomially in hospitals or nursing homes (Funke and Bernard, 2007). However, many of the medically relevant species can also be recovered as commensals or contaminants from a variety of clinical specimens. Therefore, it is recommended that identification to species level should be attempted if the organism is isolated (i) from normally sterile body sites, e.g. blood (except if only one of multiple specimens became positive), (ii) from adequately collected clinical material if the *Corynebacterium* species is the predominant organism, and (iii) if recovered from urine specimens, e.g. *Corynebacterium urealyticum* (described further below), is the sole bacterium encountered with a bacterial count >10^4/ml or if it is the predominant organism recovered and the total bacterial count is >10^5/ml (Funke and Bernard, 2007).

Corynebacterium species can cause significant infection or appear to be commensals in animals or birds. Virulence factors and mechanisms of pathogenicity remain understudied. To date, 31 species associated with animals or birds have

been described including: *Corynebacterium amycolatum* (mastitis in cattle) (Hommez et al., 1999), *Corynebacterium aquilae* and *Corynebacterium falsenii* (from eagles) (Fernández-Garayzábal et al., 2003), *Corynebacterium auriscanis* (otitis and suppurations in dogs) (Collins et al., 1999b), *Corynebacterium bovis* (mastitis and abscesses in cattle) (Watts et al., 2000), *Corynebacterium camporealensis* (mastitis in sheep) (Fernández-Garayzábal et al., 1998), *Corynebacterium canis* (dog mouth) (Funke et al., 2010a), *Corynebacterium capitovis* (sheep skin scrapings) (Collins et al., 2001a), *Corynebacterium caspium* (from a seal) (Collins et al., 2004), *Corynebacterium ciconiae* (stork trachea) (Fernández-Garayzábal et al., 2004), *Corynebacterium cystitidis* (pyelonephritis in cattle) (Yanagawa and Honda, 1978), *Corynebacterium diphtheriae* (mastitis, dermatitis, and wound infection in cattle or horses) (Corboz et al., 1996; Greathead and Bisschop, 1963; Henricson et al., 2000), *Corynebacterium felinum* (Scottish wild cat) (Collins et al., 2001b), *Corynebacterium freiburgense* (dog mouth) (Funke et al., 2009), *Corynebacterium glucuronlyticum* (genital tract of pigs) (Devriese et al., 2000), *Corynebacterium kutscheri* (rats, mice, and hamsters) (Collins and Cummins, 1986), *Corynebacterium mastitidis* (mastitis in sheep) (Fernández-Garayzábal et al., 1997). *Corynebacterium minutissimum* (mastitis in cattle) (Hommez et al., 1999), *Corynebacterium mustelae* (sepsis in ferrets) (Funke et al., 2010b), *Corynebacterium phocae* (nasal cavity of seal) (Pascual et al., 1998), *Corynebacterium pilosum* (urogenital tract of cattle) (Yanagawa and Honda, 1978), *Corynebacterium pseudotuberculosis* (ovine caseous lymphadenitis and other sheep or goat diseases) (Baird and Fontaine, 2007; Dorella et al., 2006), *Corynebacterium renale* (pyelonephritis in cattle) (Collins and Cummins, 1986), *Corynebacterium sphenisci* (from wild penguins) (Goyache et al., 2003a), *Corynebacterium spheniscorum* (from cloacae of wild penguins) (Goyache et al., 2003a), *Corynebacterium suicordis* (pericarditis, pneumonia, and lymph enlargements of pigs) (Vela et al., 2003), *Corynebacterium testudinoris* (from a tortoise) (Collins et al., 2001b), *Corynebacterium ulcerans* (goats, pigs, cattle, horses, cats, dogs, otters, and other) (Bonmarin et al., 2009; Schuhegger et al., 2009), *Corynebacterium ulceribovis* (bovine ulcers) (Yassin, 2009), *Corynebacterium urealyticum* (UTIs of dogs and cats) (Bailiff et al., 2005; Cavana et al., 2008), and *Corynebacterium vitaeruminis* (derived from cow rumen) (Collins and Cummins, 1986).

Corynebacterium species which have been recovered or detected in animals have also been documented to be potentially the cause of infection in humans by zoonotic transmission. These infections have been found to have occurred by occupationally related handling of the animals, by animal bites, or by unknown means. This has been observed with *Corynebacterium auriscanis* (Bygott et al., 2008), *Corynebacterium bovis* (Achermann et al., 2009; Bernard et al., 2002), *Corynebacterium canis* (Funke et al., 2009), *Corynebacterium diphtheriae* (Bonmarin et al., 2009), *Corynebacterium freiburgense* (Funke et al., 2009), *Corynebacterium kutscheri* (Holmes and Korman, 2007), a *Corynebacterium mastitidis*-like organism (Eguchi et al., 2008), *Corynebacterium pseudotuberculosis* (Bonmarin et al., 2009; Join-Lambert et al., 2006; Peel et al., 1997), and particularly of interest as an emerging zoonotic agent, toxigenic strains of *Corynebacterium ulcerans* (Bonmarin et al., 2009; De Zoysa et al., 2005b; Hogg et al., 2009; Wagner et al., 2001). *Corynebacterium glucuronolyticum*, *Corynebacterium minutissimum*, and *Corynebacterium urealyticum* (described further below) are usually associated with human disease, rather than animal disease, and evidence of transmission between human and animals has not been described.

Other *Corynebacterium* species have been described as being recovered from foodstuffs, the environment, or water, and some of these in turn have been widely used in industrial applications. These are *Corynebacterium callunae* (environment), *Corynebacterium glutamicum* (environment, production of glutamic acid), *Corynebacterium flavescens* (dairy products) (Collins and Cummins, 1986), *Corynebacterium casei* (soft cheeses) (Brennan et al., 2001), *Corynebacterium doosanense* (activated sludge) (Lee et al., 2009), *Corynebacterium efficiens* (environment, production of glutamic acid) (Fudou et al., 2002), *Corynebacterium glaucum* (cosmetic dye) (Yassin et al., 2003), *Corynebacterium halotolerans* (saline soil) (Chen et al., 2004), *Corynebacterium lubricantis* (coolant lubricant) (Kampfer et al., 2009), *Corynebacterium maris* (mucus of sea coral) (Ben-Dov et al., 2009), *Corynebacterium marinum* (sea sediment) (Du et al., 2010), *Corynebacterium terpenotabidum* (environment, capable of degrading squalene) (Takeuchi et al., 1999) and *Corynebacterium variabile* (formerly *Arthrobacter variabilis*, later *Corynebacterium variabilis*, from animal fodder) (Collins, 1987a).

Enrichment and isolation procedures

Members of this genus require one or more vitamins, amino acids, purines, and pyrimidines in culture medium to grow (Collins and Cummins, 1986; Funke and Bernard, 2007). Growth for some species is enhanced by the addition of lipids or by using an extended incubation period (detailed below, *Corynebacterium urealyticum* when recovered from urine). Growth is generally achieved using a temperature range from 30–37°C, particularly under a 5% CO_2 atmosphere with other ranges described as appropriate by species, below. No species described to date will grow on MacConkey agar except *Corynebacterium lubricantis* (described below). Isolation of *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, or *Corynebacterium pseudotuberculosis* from non-sterile sites is outlined below.

Maintenance procedures

Corynebacterium species in general do not require special procedures for storage. Short-term (weeks or months) storage has historically been done using enriched media such as PAIs, Loeffler's, or blood agar slants (von Graevenitz and Bernard, 2003). Medium-term storage may be done by storage of bacteria on beads in cryopreservative at −80°C (available commercially), and long-term preservation may be done by standard lyophilization procedures.

Procedures for testing special characters

Contemporary biochemical procedures for testing medically relevant species of this genus have been outlined previously (Funke and Bernard, 2007; von Graevenitz and Bernard, 2003). Rapid identification panels such as the API Coryne strip (BioMérieux) have been described for characterization of many of these species and are especially useful for those which grow well within the allotted 48 h incubation period and are reactive with the slate of substrates. Users are cautioned that the underlying database is only infrequently updated and does not provide enough discrimination to delineate among newly described species outlined here. The API Coryne strip does not

include starch utilization, a feature which historically was used in part to differentiate among biovars (= biotypes) of *Corynebacterium diphtheriae*. A web-based query to decode API data exists; it provides possible adjunct tests to assist with identification (https://apiweb.bioMerieux.com). Ancillary strips such as BioMérieux's API ZYM enzyme strip, API CH50 with API 20 E and panels manufactured by other companies, are also frequently used. The automated Biolog system has been used to provide phenotypic characteristics for various *Corynebacterium* species including the screening of nutritional and other physiological properties (Fernandez-Natal et al., 2009). Enzyme testing has been done as single test assays, such as described for pyrazinamidase or phosphatase (synonym of alkaline phosphatase) in a previous version of this chapter (Collins and Cummins, 1986). The characterization of species with no medical relevance that were derived from the environment has been carried out, either manually or by automated means (e.g. by use of the Biolog system) by testing the ability of the organism to utilize different carbon compounds, by defining optimal or preferred salinity, temperature, atmosphere, and pH, and by considering chemotaxonomic and genetic features; this has been outlined recently for *Corynebacterium lubricantis* (below) (Kampfer et al., 2009).

Metachromatic granules (synonym polymetaphosphate), the presence of which is described for some species in this text, are observed as bluish-purple after staining with methylene blue stain (Macfaddin, 2000).

Many species in this genus are lipophilic, i.e. they grow poorly at 35–37°C in 24 h or longer on standard laboratory media, but show enhanced growth in 48–72 h on sheep blood or brain heart infusion broth enriched with a lipid, such as 0.1–1.0% Tween 80, as detailed below for *Corynebacterium macginleyi* (Riegel et al., 1995e).

Special selective agars exist for *Corynebacterium* species, but the most widely used are those which select for *Corynebacterium diphtheriae* or *Corynebacterium ulcerans* from respiratory specimens, e.g. Tellerite or modified Tinsdale agars (Efstratiou and George, 1999).

The entire gene or fragments of the gene associated with the production of diphtheria toxin by *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, and *Corynebacterium pseudotuberculosis* can be detected by conventional (Efstratiou et al., 1998; Efstratiou et al., 2000) or real-time PCR (Mothershed et al., 2002; Schuhegger et al., 2008a, 2008b; Soriano et al., 2009). However, definitive toxigenic status is achieved only by detecting expression of diphtheria toxin, which is generally done using the modified Elek test (Engler et al., 1997). CAMP reaction and expression of phospholipase D by the CAMP inhibition assay for *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis* strains (Barksdale et al., 1981) are useful tests for these species.

Differentiation of the genus *Corynebacterium* from other genera

Of the 60-plus *Corynebacterium* species described since publication of the previous edition of the *Manual*, many but not all authors describe testing for the presence of corynemycolates, types of cell-wall sugars and/or types of diaminopimelic acid, types and quantities of long-chain cellular fatty acids, and G+C mol% (Table 31). Testing for other features such as for other types of cell-wall lipids or phospholipids, polyamines, or acyl types are now only infrequently done. Staining for the presence of metachromatic granules is now almost never described.

Taxonomic comments

The genus *Corynebacterium* belongs to the phylum *Actinobacteria*, class *Actinobacteria*, order *Corynebacteriales*, family *Corynebacteriaceae*. Specific 16S rRNA signature nucleotides for these bacteria have been outlined (Zhi et al., 2009).

It has become increasingly difficult to distinguish *Corynebacterium* species based on phenotypic testing alone, as shown from some of the data outlined in Table 32. Additional identification approaches, such as the use of 16S rRNA and *rpoB* gene sequencing, are being used more routinely as a significant adjunct to characterization. However, assignment of species nova to this genus requires testing for as many genetic and chemotaxonomic properties as are available to researchers, and, increasingly, full genome sequencing is highly recommended.

Many of the genera described in the previous edition of this *Manual* as being closely related to the genus *Corynebacterium* have subsequently been found to be unrelated or qualitatively distinguishable by genetic and chemotaxonomic methods. All *Corynebacterium* species previously attributed to causing disease in plants have been reassigned, and none of the species described here have been documented to be phytopathogens. *Corynebacterium* species reassigned since the previous edition to other genera include: *Corynebacterium betae*, *Corynebacterium oortii*, *Corynebacterium flaccumfaciens* Hedges 1922 and *Corynebacterium poinsettiae* to *Curtobacterum flaccumfaciens* comb. nov. Collins and Jones 1984 (Effective publication: Collins and Jones 1983b.); *Corynebacterium equi* and *Corynebacterium hoagii* to *Rhodococcus equi* (Magnusson 1928) Goodfellow and Alderson 1977[AL]; *Corynebacterium fascians* Tilford 1936 to *Rhodococcus fascians* comb. nov. Goodfellow 1984b (Effective publication: Goodfellow 1984a.); *Corynebacterium insidiosum*, *Corynebacterium michiganense*, *Corynebacterium nebraskense*, and *Corynebacterium sepedonicum* to the genus *Clavibacter* as subspecies of *Clavibacter michiganensis* (Davis et al. 1984); *Corynebacterium iranicum* to *Rathayibacter iranicus* comb. nov. Zgurskaya et al. 1993; *Corynebacterium paurometabolum* Steinhaus 1941 to *Tsukamurella paurometabolum* comb. nov. Collins et al. 1988c, later corrected to *Tsukamurella paurometabola* by Euzéby (1998); *Corynebacterium pyogenes* Glage 1903 to *Actinomyces pyogenes* Reddy et al. 1982 to *Arcanobacterium pyogenes* comb. nov. (Glage 1903) Pascual Ramos et al. 1997 and then to *Trueperella pyogenes* comb. nov. (Glage 1903) Yassin et al. 2011; *Corynebacterium rathayi* Smith 1913 to *Clavibacter rathayi* comb. nov. Davis et al. 1984 then to *Rathayibacter rathayi* comb. nov. (Smith 1913) Zgurskaya et al. 1993, and lastly, *Corynebacterium tritici* Carlson and Vidaver 1982 to *Clavibacter tritici* comb. nov. Davis et al. 1984 then to *Rathayibacter tritici* comb. nov. (Carlson and Vidaver 1982) Zgurskaya et al. 1993.

Corynebacterium ilicis was proposed as the name for a bacterial pathogen of American holly that caused a blight of foliage and twigs (Mandel et al., 1961). The type strain (DSM 20138 = ATCC 14264 = NCPPB 1228) was belatedly designated in 1977 (Dye and Kemp, 1977). Assignment of *Corynebacterium ilicis* to the genus *Corynebacterium* was controversial and subsequently it was reclassified as *Arthrobacter ilicis* Collins et al. 1981. Upon further review, the *Corynebacterium ilicis* type strain was found to

[a]Species recovered from human clinical material except as described in comment. Abbreviations and symbols: F, fermentative; O, oxidative; +, positive; –, negative; d, variable; ( ), delayed or weak reaction; nd, no data for test described; ng, no growth; REV, CAMP inhibition reaction; PYZ, pyrazinamidase; PAL, alkaline phosphatase and in older texts, was also called phosphatase; unk, unknown; TBSA, cellular fatty acid tuberculosteric acid (10-methyl 18:0) detected.

[b]*Corynebacterium diphtheriae* biovar mitis reduces nitrate but biovar belfanti is nitrate negative; all biovars of *Corynebacterium diphtheriae*, *Corynebacterium pseudotuberculosis*, and *Corynebacterium ulcerans* produce cysteinase which is detected by producing a brown-black colony with a brown black halo on cysteine-containing agar such as Tinsdale medium. These species can be lyogenized by the bacteriophage that confers ability to produce diphtheria toxin.

[c]*Corynebacterium ammoniagenes* (as *Brevibacterium ammoniagenes*) described as being completely non-reactive in sugars, and that reactivity was media dependant (Jones and Keddie, 1986).

[d]*Corynebacterium simulans*, a strong nitrite reducer at low and high concentrations may appear to be nitrate reduction negative unless further tested using zinc dust (Wattiau et al., 2000). One strain of this species was catalase negative (Bernard et al., 2002).

[e]For *Corynebacterium striatum*, the CAMP reaction, if done, has been described as negative (Martinez-Martinez et al., 1995b) or occasionally positive (Leonard et al., 1994).

[f]MDR, Multidrug resistance described at least once in the literature as being resistant to three or more drug classes using CLSI guidelines and current data (Clinical Laboratory Standards Institute, 2006, 2009).

be apathogenic for plants and a member of a different taxon group with respect to *Corynebacterium ilicis* reference strains ICMP 2608 and ICMP 2609, described at the same time as the type strain, which were pathogenic for American holly. Following Request for an Opinion no. 87 (Young et al., 2004), the Judicial Commission ruled that features associated with the name *Corynebacterium ilicis* Mandel et al. 1961 should be represented by the type strain ICMP 2608 = ICPB CI144 (later reassigned to *Curtobacterium flaccumfaciens*), and that *Arthrobacter ilicis* would be typified by strain DSM 20138 = ATCC 14264 = NCPPB 1228 (Effective publication: Collins et al., 1981.) and validated (Collins et al., 1982c; Young et al., 2004; Judicial Commission of the International Committee on the Systematics of Prokaryotes, 2008).

Brevibacterium liquefaciens Okabayashi and Masuo 1960[AL] was reclassified as *Corynebacterium liquefaciens* (Okabayashi and Masuo 1960) Lanéelle et al. 1980 based on the study of the type strain, ATCC 14929 (Lanéelle et al., 1980). This isolate was later found to have significant differences when compared to a new copy of ATCC 14929 and, as a result, all recommendations for reassignment were withdrawn in an erratum. *Brevibacterium liquefaciens* strain ATCC 14929 was subsequently reassigned to *Arthrobacter nicotianae* Giovannozzi-Sermanni 1959 by Gelsomino et al. (2004).

It is not anticipated that further changes in taxonomic classification of members of the genus *Corynebacterium* will occur except by the emendation or augmentation by new species.

List of species of the genus *Corynebacterium*

Information on this list was corroborated with by information compiled by Euzéby (2010). Accession numbers for *rpoB* gene sequences describe either complete gene (3100–3450 bp) or partial gene sequences (with ~400–425 bp).

1. **Corynebacterium diphtheriae** (Kruse 1886) Lehmann and Neumann 1896, 350[AL] ("*Bacillus diphtheria*" Kruse *in* Flügge 1886, 225)

diph.the.ri′a.e. Gr. n. *diphthera* leather, skin; N.L. fem. n. *diphtheria* a disease in which a leathery membrane forms in the throat; N.L. gen. n. *diphtheriae* of diphtheria.

(This description is largely based on that of Collins and Cummins, 1986.)

Straight or slightly curved rods, frequently swollen at one or both ends, 0.3–0.8 × 1.0–8.0 µm. Usually stains unevenly and

often contains metachromatic granules (polymetaphosphate) which stain bluish purple with methylene blue. Gram-stain-positive, but easily decolorized, especially in older cultures.

Descriptive cultural types or biovars (= biotypes) of *Corynebacterium diphtheriae* strains are still commonly applied and are designated gravis, intermedius, mitis, and belfanti. Designations for gravis, intermedius, and mitis were originally given in accordance with the clinical severity of cases from which the different strains were most frequently isolated. On blood agar, colonies vary in size and appearance but generally are 1–3 mm at 24 h (except intermedius, described below) and may demonstrate a narrow band of hemolysis, but no soluble hemolysin is produced. Colonies on blood tellurite (with 0.04% potassium tellurite) are gray to black, with appearance dependant on type. Colonies on modified Tinsdale agar are 1–2 mm, black or charcoal gray, with each colony having a brown-black halo visible in the agar as cysteinase produced by the organism reacts with the cysteine in the medium. Although less frequently used now, growth on Loeffler's medium is abundant, with grayish to cream colored colonies and no liquefaction. The use of historical descriptions of colonies (such as gravis being large, radially striated brittle colonies and mitis being smooth, shiny, and butyrous) or Gram stain details (gravis having short regular rods, intermedius with long rods with marked cross-striations, mitis with long curved irregular rods) as a means to subdivide strains into gravis, intermedius, and mitis are now rarely used.

Biovars are usually reported for clinical isolates and are generally differentiated by phenotype: biovar gravis reduces nitrate and utilizes both glycogen and starch; biovar intermedius is somewhat lipophilic in that colonies are 0.5–1 mm after 24–48 h growth on blood agar, but otherwise reduces nitrate and may utilize glycogen (rapid strip API Coryne usually negative but conventional tube sugar positive) and starch; biovar mitis reduces nitrate but does not utilize glycogen and rarely starch; biovar belfanti neither reduces nitrate nor utilizes glycogen or starch. CAMP and CAMP inhibition reactions negative. All strains exhibit the same reactions except for occasional sucrose-fermenting isolates described primarily in South America (de Mattos-Guaraldi and Formiga, 1998) or *Corynebacterium diphtheriae* biovar belfanti like isolates that were derived from symptomatic cats and did not ferment maltose (Hall et al., 2010). Optimal growth temperature 30–37°C, and complex media is required for growth.

All *Corynebacterium diphtheriae* strains, regardless of biovar, conform to the genus description chemotaxonomically. All contain corynemycolates, the polar lipids phosphatidylglycerol, phosphatidylinositol, and monoacylated phosphatidylinositol dimannoside, and MK-8 (H2) as major menaquinone. Cell wall contains *meso*-diaminopimelic acid and the sugars arabinose and galactose. Straight-chain saturated fatty acids are mainly palmitic and stearic acids with minimal branched saturated fatty acids; significant quantities of $C_{16:1}$ ω7*c* isomer is characteristically detected (Bernard et al., 1991). All produce propionic as a product of fermentation (Bernard et al., 2002).

Source: clinical specimens from humans or animals.

DNA G+C content (mol%): 52–55 (method unknown); 53.48 (full genome sequencing).

Type strain: ATCC 27010, CIP 100721, DSM 44123, NCTC 11397.

Sequence accession no. (16S rRNA gene): GQ118341, X82059, X84248.

Further comments: additional GenBank accession numbers include (complete genome sequence) BX248353 and (complete *rpoB* gene) AY492230. All biovars of *Corynebacterium diphtheriae* may produce diphtheria toxin which clinically should be tested for as described elsewhere in this chapter. Non-toxigenic strains otherwise have typical features. Full genome sequence of *Corynebacterium diphtheriae* strain NCTC 13129 has been published containing 2,488,635 bp (Cerdeno-Tarraga et al., 2003).

2. **Corynebacterium accolens** Neubauer, Sourek, Ryc, Bohacek, Mara and Mnukova 1991a, 331[VP] (Effective publication: Neubauer, Sourek, Ryc, Bohacek, Mara and Mnukova 1991b, 50.)

ac′co.lens. L. v. *accolere* live by; L. part. adj. *accolens* living close by.

Cells are Gram-stain-positive rods, 0.6–0.9 × 1.0–2.0 µm, nonmotile, occurring singly or in clusters typical for corynebacteria. Colonies are roundish, slightly convex, grayish, and show the phenomenon of satellitism, i.e., enhanced growth in the vicinity of *Staphylococcus aureus* indicating that the strains are lipophilic. Facultatively anaerobic. Oxidase negative. Growth occurs at 30–40°C with optimal growth at 37°C, pH 7.2. Acid is produced from D-glucose, galactose, fructose, D-mannose, and maltose. Fermentation of sucrose is variable. Acid is not produced from lactose, D-xylose, trehalose, L-arabinose, raffinose, L-rhamnose, dextrin, mannitol, dulcitol, D-sorbitol, glycerol, *myo*-inositol, salicin, and inulin. Esculin, urea, gelatin, casein, and starch are not hydrolyzed. No production of indol, H_2S, acetoin, and lipase. The methyl red test is negative. CAMP reaction negative. Cell wall contains *meso*-diaminopimelic acid; corynemycolic acids made up of 22–36 carbon atoms and arabinose and galactose sugars. Cellular fatty acids are as described for the genus. Menaquinone or polar lipid types not extant. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human clinical specimens, in particular specimens from ear, nose, throat, and eyes.

DNA G+C content (mol%): 53.2 (method unknown).

Type strain: CNCTC Th1/57, ATCC 49725, CCUG 28779, CIP 104783, DSM 44278, JCM 8331.

Sequence accession no. (16S rRNA gene): AJ439346, X80500.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492242. *rpoB* gene sequencing should be done to distinguish strains from *Corynebacterium macginleyi*, as those species can not be easily distinguished by 16S rRNA gene sequencing.

3. **Corynebacterium afermentans** Riegel, de Briel, Prévost, Jehl, Monteil and Minck 1993b, 291[VP]

a.fer.men′tans. Gr. pref. *a* not; L. part. adj. *fermentans* leavening; N.L. part. adj. *afermentans* nonfermenting; i.e. nonfermenting carbohydrates.

The bacteria are Gram-stain-positive irregular rods or coccobacilli that sometimes contain metachromatic granules. Cells are arranged in typical V-shaped forms or palisades. Nonlipophilic. Good growth under aerobic conditions, and very slight growth under anaerobic conditions.

Smooth, grayish-white colonies with entire margins. Colonies are 1–2 mm in diameter. Acid is not produced from glucose, glycogen, lactose, sucrose, ribose, D-xylose, D-mannose, D-galactose, trehalose, and D-mannitol. Cells utilize acetate and lactate. Propionate, D-glucose, L-arabinose, D-mannose, D-mannitol, *N*-acetylglucosamine, maltose, gluconate, caprate, adipate, malate, citrate, and phenylacetate are not utilized. Nitrate is not reduced. Urea and esculin not hydrolyzed. Tyrosine, gelatin, DNA, and starch are not degraded. The methyl red test is negative, and acetoin, indole, and H_2S (on triple-sugar iron agar) are not produced. Hydrolysis of hippurate is variable. Growth is visible in 6.5% NaCl. Alkaline phosphatase, esterase, lipase, and acid phosphatase are produced. α-Galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, and β-glucosidase are not produced. All strains are resistant to fosfomycin. CAMP reaction variable (Funke and Bernard, 2007).

The cell wall contains *meso*-diaminopimelic acid, arabinose, and galactose. Cellular fatty acids are consistent with those described for the genus. Corynemycolates are present with $C_{30:0}$, $C_{30:1}$, $C_{32:1}$, $C_{33:1}$, $C_{34:2}$, and $C_{36:2}$ predominating. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): 66 (HPLC).

Type strain: ATCC 51403, CCUG 32103, CIP 103499, DSM 44280, JCM 10390, LCDC 88199.

Sequence accession no. (16S rRNA gene): X82054.

Further comments: Corynebacterium afermentans Riegel et al. (1993b) was previously known as CDC coryneform ANF-1. By 16S rRNA gene sequencing, *Corynebacterium afermentans* is closely related to (98% identity with) to *Corynebacterium coyleae* and *Corynebacterium mucifaciens* but differs (~94% identity with) when *rpoB* gene sequences are compared (Khamis et al., 2004) and by phenotypic testing (Table 32).

3a. **Corynebacterium afermentans subsp. afermentans** Riegel, de Briel, Prévost, Jehl, Monteil and Minck 1993b, 291[VP]

a.fer.men′tans. Gr. pref. *a* not; L. part. adj. *fermentans* leavening; N.L. part. adj. *afermentans* nonfermenting; i.e. nonfermenting carbohydrates.

Colonies are 1–2 mm in diameter after 24 h on blood agar and are not lipophiilc.

Source: human clinical specimens.

DNA G+C content (mol%): 66 (HPLC).

Type strain: ATCC 51403, CCUG 32103, CIP 103499, DSM 44280, JCM 10390, LCDC 88199.

Sequence accession no. (16S rRNA gene): X82054.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492265.

3b. **Corynebacterium afermentans subsp. lipophilum** Riegel, de Briel, Prévost, Jehl, Monteil and Minck 1993b, 291[VP]

li.po′phi.lum. Gr. n. *lipos* animal fat; Gr. neut. adj. *philon* loving; N.L. neut. adj. *lipophilum* fat loving.

The characteristics of *Corynebacterium afermentans* subsp. *lipophilum* are similar to those of *Corynebacterium afermentans* subsp. *afermentans* except that very small colonies (<0.5 mm in diameter) appear after 48 h on sheep blood agar. Strains are lipophilic. Hippurate is not hydrolyzed.

Chemotaxonomic features are like those of *Corynebacterium afermentans* subsp. *afermentans* except that branched saturated fatty acids are heptadecanoic acid, and straight-chain unsaturated fatty acids are mainly oleic acid, linoleic acid, and arachidonic acid.

Source: human clinical specimens.

DNA G+C content (mol%): 68 (HPLC).

Type strain: T18502, ATCC 51404, CCUG 32105, CIP 103500, DSM 44282, JCM 10391.

Sequence accession no. (16S rRNA gene): X82055.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492266.

4. **Corynebacterium ammoniagenes** (Cooke and Keith 1927) Collins 1987b, 442[VP] ("*Bacterium ammoniagenes*" Cooke and Keith 1927)

am.mo.ni.a′ge.nes. N.L. n. *ammonia* ammonia; N.L. suff. *-genes* (from Gr. v. *gennaô* to produce) producing; N.L. part. adj. *ammoniagenes* ammonia-producing.

Gram-stain-positive, nonsporeforming, nonmotile rod-shaped cells (1–4.5 × 0.6 –1.2 µm in diameter). Cells are irregular and occur singly or in pairs and may exhibit V forms. Colonies are circular, low convex with an entire edge, and are gray-white or yellow. Facultatively anaerobic. Optimum growth temperature is approximately 30°C. Growth occurs at 10°C and 37°C but not at 45°C. Growth occurs in the presence of 10% NaCl. Fermentation of carbohydrates has been described as being equivocal (Collins, 1987b). In a recent study, the following reactions were found for ATCC 6871^T: glucose, ribose, and fructose were slowly fermented, but xylose, mannitol, lactose, maltose, galactose, glycerol, glycogen, raffionse, salicin, trehalose, and mannose were not. Nitrate reduced to nitrite. Urease is produced. Hippurate and tyrosine are hydrolyzed. Gelatin, casein, DNase, and starch are not hydrolyzed. Citrate is alkalinized. CAMP and reverse CAMP reactions are negative. Leucine arylamidase positive, but pyrazinamidase, pyrrolidonyl arylamidase, alkaline phosphatase, esterase, esterase lipase, lipase, valine arylamidase, cystine arylamidase, trypsin, alpha chymotrypsin, acid phosphatase, naphthol-AS-Bl-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase not detected (Bernard et al., 2010). Some organic acids may be assimilated.

Cell wall contains *meso*-DAP. The glycan moiety of murein contains only acetyl residues. Cell wall contains arabinogalactan polymer. Corynomycolic acids are present. Long-chain fatty acids are of the saturated, monounsaturated, and 10-methyl-branched types with hexadecanoic, octadecanoic, octadecenoic, and 10-methyl-octadecanoic acids predominating. TBSA detected but does not produce propionic acid as metabolic product (Bernard et al., 2010). The major phospholipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol dimannoside. The major menaquinone is MK-9(H_2).

Source: feces of infants and piggery waste.

DNA G+C content (mol%): 53.7–55.8 (T_m).

Type strain: ATCC 6871, CCUG 38796, CIP 101283, DSM 20306, JCM 1305, NBRC 12612, NCCB 60030, NCIMB 8143, VKM B-672.

Sequence accession no. (16S rRNA gene): X84440.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492243 and (partial *rpoB* gene) FJ648511.

5. **Corynebacterium amycolatum** Collins, Burton and Jones 1988b, 449[VP] (Effective publication: Collins, Burton and Jones 1988a, 351.)

a.my.co′la.tum. N.L. neut. adj. *amycolatum* wanting in mycolates.

Cells are Gram-stain-positive, nonmotile, nonsporeforming, pleomorphic rods. Colonies are whitish-grayish, dry, rough, and with uneven edges. Facultatively anaerobic. Nonlipophilic. Grows at 37°C but not at 10°C or 20°C at 3 d (Wauters et al., 1998); some strains grow at 40°C. Grows in 5% NaCl; some strains grow in 10% NaCl. Acid is usually produced from D-fructose, D-glucose, glycerol, D-mannose, and ribose. Acid production from maltose, sucrose, galactose (Wauters et al., 1996), and trehalose is variable. Acid is not produced from *N*-acetylglucosamine, starch, amygdalin, D-arabinose, L-arabinose, D-arabitol, L-arabitol, arbutin, cellobiose, D-fucose, L-fucose, b-gentiobiose, glycogen, gluconate, 2-keto-gluconate, 5-keto-gluconate, inositol, inulin, lactose, D-lyxose, mannitol, melezitose, melibiose, α-methyl-D-glucoside, α-methyl-D-mannoside, β-methyl xyloside, D-raffinose, rhamnose, salicin, sorbitol, L-sorbose, xylitol, D-xylose, and L-xylose. Glucose may be fermented at 42°C and ethylene glycol may be acidified at 48 h (Wauters et al., 1998). CAMP reaction is negative. Nitrate reduction and urea hydrolysis are variable. Esculin, arginine, casein, cellulose, gelatin, ornithine, tyrosine, and xanthine are not hydrolyzed. Starch is hydrolyzed (Funke et al., 1996a). Some strains hydrolyze hippurate. Pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, cystine arylamidase, and acid phosphatase are detected; lipase, leucine arylamidase, and phosphoamidase are variable, but valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not detected (Funke et al., 1996a). Voges–Proskauer and methyl red positive.

Cell-wall peptidoglycan contains *meso*-diamimopimelic acid, alanine, and glutamic acid. Arabinose and galactose are wall sugars. Mycolic acids are not present. The cellular fatty acids are consistent with those described for the genus. The principle menaquinone is MK-9(H_2) with significant quantities of MK-8(H_2). Polar lipid types include acyl phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol dimannoside, and several unknown phospholipids (Collins et al., 1988a; Yague et al., 1997). Strains produce propionic acid as a product of fermentation (Funke et al., 1996a).

Source: human clinical specimens; also recovered from animals (Hommez et al., 1999).

DNA G+C content (mol%): 61 (T_m).

Type strain: S160, ATCC 49368, CCUG 35685, CIP 103452, DSM 6922, JCM 7447, NBRC 15207, NCIMB 13130.

Sequence accession no. (16S rRNA gene): X82057.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492241. When identification is done based solely on the use of phenotypic methods, *Corynebacterium amycolatum* isolates have been misidentified as *Corynebacterium xerosis*, *Corynebacterium minutissimum*, *Corynebacterium striatum*, and other closely related taxa (Funke et al., 1996a; Wauters et al., 1996; Zinkernagel et al., 1996). Most strains identified as *Corynebacterium amycolatum* using a polyphasic approach are MDR due in part to the presence of the *ermX* gene and other mechanisms as yet not fully elaborated (Yague et al., 1997). Older publications where identification of *Corynebacterium xerosis* and *Corynebacterium minutissimum* was based on biochemical, not genetic, traits should be interpreted with caution, as strains described as being multidrug resistant may, in fact, be misidentified *Corynebacterium amycolatum* isolates. The *Corynebacterium amycolatum* type strain (CCUG 35685[T]) and at least one other reference strain, CIP 100836 ("*Corynebacterium asperum*"), differ from most clinical isolates as they are fully sensitive to all drug classes tested by microbroth dilution (K. Bernard, personal communication). Strains formerly designated CDC group I2 or CDC group F2 have been assigned to *Corynebacterium amycolatum* (Wauters et al., 1996).

6. **Corynebacterium appendicis** Yassin, Steiner and Ludwig 2002b, 1168[VP]

ap.pen′di.cis. L. fem. gen. n. *appendicis* of an appendage, intended to mean pertaining to appendicitis, from which the patient from whom the clinical material was taken for isolation of the organism was suffering.

Cells are Gram-stain-positive, thin, nonmotile, nonsporeforming, and pleomorphic coryneforms. Form small (<0.5 mm in diameter), grayish, and nonhemolytic colonies on Columbia sheep blood agar after 2 d at 37°C. Lipophilic. Facultatively anaerobic. Nitrate is not reduced. Acid is produced from glucose, maltose, and glycerol but not from arabinose, arabitol, cellobiose, glycogen, inulin, lactose, mannitol, melibiose, melzitose, pullulan, salicin, sorbitol, sucrose, tagatose, trehalose, raffinose, rhamnose, ribose, or xylose. Does not hydrolyze esculin, gelatin, hippurate, or starch. Displays urease, alkaline phosphatase, and pyrazinamidase activities but not acid phosphatase, arginine dihydrolase, esterase, esterase lipase, lipase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, phosphoamidase, alanine-phenylalanine-proline arylamidase, glycyl-tryptophan arylamidase, pyroglutamic acid arylamidase, pyrrolidonyl arylamidase, valine arylamidase, cystine arylamidase, leucine arylamidase, trypsin, and chymotrypsin. Acetoin production is positive, but indole production is negative. Produces lactate, but not propionate, as the major product of glucose fermentation.

Contains *meso*-DAP as wall diamino acid in addition to galactose and arabinose in whole-cell hydrolysates (i.e. cell-wall chemotype IV). Corynomycolic acids are present, and the fatty acid profile contains saturated, unsaturated, and huge amounts of tuberculostearic acids. Type PI phospholipids pattern with no nitrogen-containing compounds.

Source: abdominal swab of a patient with appendicitis with abscess formation.

DNA G+C content (mol%): 65.8 (HPLC).

Type strain: CCUG 48298, DSM 44531, IMMIB R-3491, JCM 11765, NRRL B-24151.

Sequence accession no. (16S rRNA gene): AJ314919.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EU004066.

7. **Corynebacterium aquilae** Fernández-Garayzábal, Egido, Vela, Briones, Collins, Mateos, Hutson, Domínguez and Goyache 2003, 1137[VP]

a.qui′la.e. L. gen. n. *aquilae* of an eagle.

Cells are Gram-stain-positive, nonmotile, nonsporeforming rods. Colonies are whitish, low convex, nonhemolytic, dry, and rough, 1–2 mm in diameter after 48 h incubation at 37°C. Facultatively anaerobic. Oxidase negative. Nonlipophilic. CAMP reaction is negative. Nitrate is not reduced. Acid is produced from D-glucose, D-fructose, D-mannose, glycerol, ribose, *N*-acetylglucosamine, and galactose, but not from maltose, trehalose, D-xylose, L-xylose, mannitol, lactose, sucrose, erythritol, D-arabinose, L-arabinose, adonitol, methyl β-xyloside, L-sorbose, rhamnose, inositol, sorbitol, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, arbutin, salicin, cellobiose, melibiose, inulin, melezitose, D-raffinose, xylitol, b-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, 2-keto-gluconate, 5-keto-gluconate, and glycogen. Esculin, urea, and gelatin are not hydrolyzed. Alkaline and acid phosphatases, esterase, esterase lipase, leucine arylamidase, chymotrypsin, and phosphoamidase activities are detected. No activity is detected for lipase, α-glucosidase, β-glucosidase, β-glucuronidase, α-mannosidase, α-galactosidase, β-galactosidase, α-fucosidase, *N*-acetyl- β-glucosaminidase, valine arylamidase, cystine arylamidase, and trypsin.

The cell wall contains *meso*-DAP. Mycolic acids (C_{30}-C_{36}) are present. Fatty acids are of the straight-chain saturated ($C_{14:0}$, $C_{16:0}$, and $C_{18:0}$) and monounsaturated ($C_{16:1}$ ω9*c* and $C_{18:1}$ ω9*c*) types.

Source: eagles.

DNA G+C content (mol%): not available.

Type strain: S-613, CCUG 46511, CECT 5993, JCM 12268.

Sequence accession no. (16S rRNA gene): AJ496733.

8. **Corynebacterium argentoratense** Riegel, Ruimy, de Briel, Prévost, Jehl, Bimet, Christen and Monteil 1995a, 537[VP]

ar.gen.to.ra.ten′se. L. neut. adj. argentoratense of or pertaining to *Argentoratus*, Latin name of the city of Strasbourg, where the organism was isolated.

Cells are Gram-stain-positive, nonmotile, nonsporeforming pleomorphic rods. They grow on blood agar as circular acuminated creamy colonies which are not hemolytic. Facultatively anaerobic. Nonlipophilic. Nitrate is not reduced. Esculin, urea, gelatin, tyrosine, and DNA are not hydrolyzed or degraded. Hydrolyses of starch and hippurate occur variably. Acid is produced from D-glucose and fructose but not from sucrose, maltose, lactose, galactose, D-xylose, trehalose, glycogen, or D-mannitol. Acidification from ribose occurs variably. Pyrazinamidase, esterase lipase, cystine arylamidase, and, characteristically, α-chymotrypsin are present. Production of esterase, leucine arylamidase, and acid phosphatase is variable, and alkaline phosphatase is usually not produced. Pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, and *N*-acetyl- β-glucosaminidase are not produced.

The cell wall contains *meso*-DAP and the sugars arabinose and galactose. Mycolic acids of short-chain lengths (C_{26}–C_{36}) are present. Strains produce propionic acid as a metabolic product (Bernard et al., 2002).

Source: human clinical specimens, in particular throat specimens.

DNA G+C content (mol%): 60–61 (HPLC).

Type strain: IBS B10697, ATCC 51927, CCUG 34893, CIP 104296, DSM 44202, JCM 10392.

Sequence accession no. (16S rRNA gene): X83955.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492249.

9. **Corynebacterium atypicum** Hall, Collins, Hutson, Lawson, Falsen and Duerden 2003, 1067[VP]

a.ty′pi.cum. N.L. neut. adj. *atypicum* not typical, referring to the absence of corynomycolic acids, a feature normally present in corynebacteria.

Cells are Gram-stain-positive, short to filamentous rods. Colonies on Columbia agar with 5% horse blood, after incubation at 37°C for 48 h, are pinpoint, convex, entire-edged, shiny, white, and nonhemolytic. Facultatively anaerobic. Nonlipophilic. Growth occurs in broth containing 7.5% NaCl but not in 10% NaCl. Nitrate is not reduced to nitrite. Esculin, urea, gelatin, and starch are not hydrolyzed. Acid is produced from D-glucose, maltose, ribose, and sucrose but not from lactose, mannitol, glycogen, or D-xylose. Activity is detected for β-glucuronidase, cystine arylamidase, leucine arylamidase, and valine arylamidase. Alkaline and acid phosphatases, chymotrypsin, esterase, esterase lipase, α-fucosidase, α-galactosidase, β-galactosidase, a-glucosidase, β-glucosidase, lipase, α-mannosidase, *N*-acetyl-β-glucosaminidase, phosphoamidase, pyrrolidonyl arylamidase, pyrazinamidase, and trypsin are not produced. Acetoin is not produced.

The cell-wall murein contains *meso*-DAP. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present. Mycolic acids are not detected.

Source: an unknown human clinical source; habitat is not known.

DNA G+C content (mol%): not available.

Type strain: R2070, CCUG 45804, CIP 107431, JCM 12368.

Sequence accession no. (16S rRNA gene): AJ441057.

10. **Corynebacterium aurimucosum** Yassin, Steiner and Ludwig 2002a, 1004[VP] emend. Daneshvar, Hollis, Weyant, Jordan, MacGregor, Morey, Whitney, Brenner, Steigerwalt, Helsel, Raney, Patel, Levett and Brown 2005, 7 (Effective publication: Daneshvar, Hollis, Weyant, Jordan, MacGregor, Morey, Whitney, Brenner, Steigerwalt, Helsel, Raney, Patel, Levett and Brown 2004, 4197.)

au.ri.mu.co′sum. L. n. *aurum* gold; L. neut. adj. *mucosum* slimy; N.L. neut. adj. *aurimucosum* slimy and gold-colored, pertaining to the appearance of colonies.

Cells are Gram-stain-positive and non-acid-fast. They are thin, nonmotile, nonsporeforming, and pleomorphic coryneforms. On Columbia blood agar supplemented with 5% sheep blood, the colonies are sticky and slightly yellow or charcoal black in color. On trypticase soy agar, they appear colorless or charcoal black and slimy. On brain heart infusion agar supplemented with 1% Tween 80, some strains are able to form a corraloid precipitin in agar when grown in the presence of CO_2. Facultatively anaerobic. Oxidase very rarely positive. Acid is produced from fructose, D-glucose, maltose, sucrose, and occasionally D-mannitol but not from adonitol, amygdalin, arabinose, cellobiose, glycerol, glycogen, inulin, lactose, mannose, melezitose,

raffinose, rhamnose, ribose, salicin, sorbitol, trehalose, or xylose. Hydrolyzes hippurate and occasionally gelatin and urea but not starch. Esculin hydrolysis is variable, and nitrate reductase is rare. Positive for alkaline phosphatase, leucine arylamidase, and pyrazinamidase activities, but negative for acid phosphatase, arginine dihydrolyse, esterase, ester lipase, lipase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, phosphoamidase, pyrrolidonyl arylamidase, valine arylamidase, cystine arylamidase, trypsin, and chymotrypsin. Acetoin positive and indole negative. Lactate, not propionate, is the major end product of glucose fermentation.

Cells contain *meso*-DAP with galactose and arabinose sugars in whole-cell hydrolysates (i.e. the cell-wall chemotype is chemotype IV). Short-chain corynomycolic acids are present. The fatty acid profile contains saturated, unsaturated, and tuberculostearic acids. It has type PI phospholopid pattern with no nitrogen-containing compounds.

Source: human clinical specimens; black-pigmented colony types are from female urogenital sites, some of which are associated with complications in pregnancy.

DNA G+C content (mol%): 63.7 (HPLC); 60.6 by complete genome sequence analysis of strain CN-1.

Type strain: CCUG 47449, DSM 44532, IMMIB D-1488, JCM 11766, NRRL B-24143.

Sequence accession no. (16S rRNA gene): AJ309207.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492282. *Corynebacterium nigricans* (Shukla et al. 2004) (Effective publication: Shukla et al. 2003.) was reassigned as a later heterotypic synonym of *Corynebacterium aurimucosum* (Yassin et al. 2002a), Daneshvar 2005 (Effective publication: Daneshvar et al. 2004.). The complete genome of a black-pigmented *Corynebacterium aurimucosum* strain CN-1 (= ATCC 700975, type strain of *Corynebacterium nigricans*) with 2,790,189 bp has been deposited under GenBank accession no. CP001601 (Trost et al., 2010). By 16S rRNA gene sequencing alone, this species can not be readily discerned from *Corynebacterium minutissimum* and *Corynebacterium singulare*, but these species can be resolved using *rpoB* gene sequencing (Khamis et al., 2004).

11. **Corynebacterium auris** Funke, Lawson and Collins 1995c, 738[VP]

au′ris. L. gen. fem. n. *auris* of the ear.

Gram-stain-positive, nonmotile, nonsporeforming diphtheroids. Colonies are circular, convex, and dry, becoming slightly yellowish with time; slightly adhere to agar. Weakly adherent if subcultured on agar plates. Nonlipophilic. Oxidative metabolism. Acid is not produced from glucose, maltose, sucrose, mannitol, xylose, ribose, lactose, and glycogen. The following substrates are utilized: γ-hydroxybutyric acid, L-malic acid, pyruvic acid, succinamic acid, *N*-acetyl-L-glutamic acid, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, and L-pyroglutamic acid. Nitrate is not reduced. Urea and esculin are not hydrolyzed. The CAMP reaction is positive. Pyrazinamidase, alkaline and acid phosphatases, esterase, esterase lipase, lipase, leucine arylamidase, and phosphoamidase are produced.

The cell wall contains *meso*-DAP. Mycolic acids are produced but are cleaved at the temperature (300°C) produced in the injection port of the commercial MIDI system, resulting in fatty acids which are identified as, e.g. $C_{17:1}$ ω6*c*–$C_{17:1}$ ω9*c* (Funke and Bernard, 2007). Cellular fatty acids are consistent with those described for the genus. Propionic acid not detected as metabolic product (Bernard et al., 2002).

Source: outer ear channel of humans.

DNA G+C content (mol%): 68–74 (HPLC).

Type strain: strain ATCC 51966, CCUG 33426, CIP 104632, DMMZ 328, DSM 44122, JCM 11946, LMG 19072.

Sequence accession no. (16S rRNA gene): X81873.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492234. *Corynebacterium auris* was originally described as Coryneform CDC group ANF-1 like.

12. **Corynebacterium auriscanis** Collins, Hoyles, Lawson, Falsen, Robson and Foster 2000, 423[VP] (Effective publication: Collins, Hoyles, Lawson, Falsen, Robson and Foster 1999b, 3446.)

au.ris.ca′nis. L. fem. n. *auris* ear; L. masc. n. *canis* dog; N.L. gen. n. *auriscanis* of the ear of the dog.

Cells are Gram-stain-positive typically club-shaped rods, which appear as single cells, in pairs, or in clusters. Obligately aerobic. Nonlipophilic. CAMP reaction negative. Acid is produced from glucose but not from glycogen, lactose, maltose, mannitol, sucrose, ribose, or D-xylose. Nitrate is not reduced, and the Voges–Proskauer test is negative. Hippurate is hydrolyzed. Esculin hydrolysis is variable. Urea, gelatin, and starch are not hydrolyzed. Alkaline and acid phosphatases, esterase (weak reaction), ester lipase (weak reaction), leucine arylamidase, phosphoamidase, and pyrrolidonyl arylamidase activities are detected. *N*-Acetyl-β-glucosaminidase, chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, α-mannosidase, pyrazinamidase, trypsin, and valine arylamidase activities are not detected. Lipase activity variable.

The cell wall contains *meso*-DAP. Short-chain mycolic acids (C_{28}–C_{34}) are present, with $C_{30:0}$, $C_{32:0}$, and $C_{34:0}$ as the main components. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present.

Source: clinical specimens from dogs; habitat is not known.

DNA G+C content (mol%): 61 (T_m).

Type strain: M598/96/1, CCUG 39938, CIP 106629, DSM 44609, JCM 12369.

Sequence accession no. (16S rRNA gene): AJ243819.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492244.

13. **Corynebacterium bovis** Bergey, Harrison, Breed, Hammer and Huntoon 1923, 388[AL]

bo′vis. L. n. *bos* a cow; L. gen. n. *bovis* of a cow.

(This description is largely based on that of Collins and Cummins, 1986.)

Irregular rods 0.5–0.7 × 2.5–3.0 μm, often clubbed shaped; coccobacillary forms may occur. Colonies on nutrient agar supplemented with Tween 80 (0.1%) are white to cream, circular, entire, slightly shiny, ~1–2 mm in diameter. Aerobic. Lipophilic. Most strains ferment glucose, fructose, galactose, maltose, and glycerol. Oxidase, arabinose, lactose, trehalose, and dextrin variable. Xylose, rhamose,

lactose, mannitol, mannose, sucrose, raffinose, salicin, and starch not utilized. Esculin, starch, and casein not hydrolyzed. Hippurate hydrolyzed; phosphatase and pyrazinamidase positive, but variable for β-galactosidase. Nitrate not reduced; urease not produced (Collins and Cummins, 1986; Hollis and Weaver, 1981).

The cell wall contains *meso*-DAP (variation A1γ), with sugars arabinose and galactose. Low-molecular-weight mycolic acids (~C_{22}–C_{36}) found, with the α-alkyl group side-chain consisting of C_6H_{13} and C_8H_{17}. MK-9 (H2) detected. Cellular fatty acids are consistent with those described for the genus (Bernard et al., 1991), with TBSA being detected. Propionic acid not detected as metabolic product (Bernard et al., 2002).

Source: aseptically drawn milk, as a commensal on cow's udder or as cause of bovine mastitis and occasionally as cause of infection in humans (Achermann et al., 2009; Bernard et al., 2002; Dutly et al., 2003; Vale and Scott, 1977).

DNA G+C content (mol%): 67.8–69.7 (T_m).

Type strain: ATCC 7715, CCUG 2705, CIP 54.80, DSM 20582, JCM 11947, NCTC 3224.

Sequence accession no. (16S rRNA gene): X84444.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492236.

14. **Corynebacterium callunae** (Lee and Good, 1963) Yamada and Komagata 1972, 412[AL] ("*Corynebacterium callunae*" Lee and Good 1963, 1349.)

cal.lu′na.e. N.L. n. *calluna* generic name of heather; N.L. gen. n. *callunae* of heather.

(This description is largely based on that of Collins and Cummins, 1986.)

Short, strongly Gram-stain-positive rods, metachromatic granules present. Moderate growth on nutrient agar. Glucose, fructose, mannose, maltose, sucrose, trehalose, salicin, and methyl red positive. Hippurate hydrolyzed and urease produced. Negative for arabinose, xylose, rhamnose, galactose, lactose, raffinose, dextrin, and starch fermentation. Esculin, casein, and gelatin hydrolysis negative, and nitrate not reduced. Grows at pH 6 and in 30% glucose but not at 45°C (Fudou et al., 2002).

Cell wall contains *meso*-DAP. Arabinose and galactose are major sugars. Mycolates are present. Cellular fatty acids are consistent with those of the genus. Menaquinone is MK-9(H_2).

Source: heather; habitat remains unknown.

DNA G+C content (mol%): 51.2 (T_m).

Type strain: ATCC 15991, CCUG 28793, CIP 104277, DSM 20147, HAMBI 2053, JCM 9489, NBRC 15359.

Sequence accession no. (16S rRNA gene): X84251.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492245.

15. **Corynebacterium camporealensis** Fernández-Garayzábal, Collins, Hutson, Gonzalez, Fernández and Domínguez 1998, 466[VP]

cam.po.re.al.en′sis. N.L. adj. *camporealensis* pertaining to Campo Real, Madrid, Spain.

Gram-stain-positive pleomorphic rods occurring singly or are arranged in palisades or V-shaped forms. Colonies are nonhemolytic, circular, slightly convex, smooth, and with a creamy consistency. Facultatively anaerobic. Nonlipophilic. CAMP reaction is strongly positive. Nitrate is not reduced. Esculin, urea, and gelatin are not hydrolyzed. Acetoin and indole are not produced. Acid is produced from glucose, but not from ribose, xylose, mannitol, lactose, maltose, sucrose, and glycogen. Pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, lipase, leucine arylamidase, valine arylamidase, and cystine arylamidase are produced. Pyrrolidonyl arylamidase, acid phosphatase, β-glucuronidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, α-mannosoidase, α-fucosidase, *N*-acetyl-β-glucosaminidase, trypsin, and chymotrypsin are not produced.

The cell wall contains *meso*-diaminopimelic acid. Short-chain mycolic acids are present.

Source: milk of sheep affected with subclinical mastitis.

DNA G+C content (mol%): not available.

Type strain: CRS-51, ATCC BAA-77, CCUG 39412, CECT 4897, CIP 105508, DSM 44610, JCM 11664.

Sequence accession no. (16S rRNA gene): Y09569.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492246.

16. **Corynebacterium canis** Funke, Englert, Frodl, Bernard and Stenger 2010a, 2546[VP]

ca′nis. L. gen. n. *canis* of a dog.

Cells are Gram-stain-positive, nonsporeforming, and nonmotile. Some cells are typically club-shaped, rods but some are filamentous, and some even show branching. Colonies are beige-whitish, dryish, with irregular edges, convoluted, up to 1–2 mm in diameter after 48 h incubation, and adherent to sheep blood agar. Facultatively anaerobic. Catalase positive. Acid is produced from glycerol, galactose, glucose, fructose, mannose, arbutin, salicin, maltose, sucrose, trehalose, starch, glycogen, tagatose, and 5-keto-gluconate but not from erythritol, arabinose, ribose, xylose, adonitol, methyl-β-D-xylopyranoside, L-sorbose, inositol, D-mannitol, D-sorbitol, methyl-α-D-mannopyranoside, methyl-α-D-glucopyranoside, *N*-acetylglucosamine, amygdalin, D-cellobiose, D-lactose, D-melibiose, inulin, D-melezitose, xylitol, gentiobiose, D-turanose, D-lyxose, fucose, arabitol, gluconate, and 2-keto-gluconate. Activities of the following enzymes can be detected: nitrate reductase, pyrazinamidase, β-glucosidase, α-glucosidase, alkaline phosphatase, esterase, esterase lipase, leucine arylamidase, trypsin, and phosphoamidase. Activities of urease, pyrrolidonyl arylamidase, gelatinase, lipase, cystine arylamidase, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not detected. The CAMP reaction is negative.

The cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus.

Source: a patient's wound after a dog bite.

DNA G+C content (mol%): not available.

Type strain: 1170, CCUG 58627, DSM 45402.

Sequence accession no. (16S rRNA gene): GQ871934.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) GQ871935.

17. **Corynebacterium capitovis** Collins, Hoyles, Foster, Sjödén and Falsen 2001a, 858[VP]

ca.pit.o′vis. L. gen. n. *capitis* of a head; L. gen. n. *ovis* of a sheep; N.L. gen. n. capitovis of a sheep's head.

Cells are Gram-stain-positive diphtheroids. Colonies are circular, entire, convex, nonhemolytic, and lemon-pigmented. Facultatively anaerobic. Nonlipophilic. Acid is produced from glucose but not from lactose, maltose, mannitol, ribose, sucrose, and D-xylose. Nitrate is not reduced. Esculin, urea, and gelatin are not hydrolyzed. Activity for alkaline and acid phosphatases, esterase (weak), esterase lipase, lipase (weak), and leucine arylamidase is detected. No activity is detected for cystine arylamidase, chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, α-mannosidase, *N*-acetyl-β-glucosaminidase, valine arylamidase, pyrazinamidase, phosphoamidase, pyrrolidonyl arylamidase, and trypsin.

Cell wall contains *meso*-DAP. Long-chain fatty acids are of the straight-chain saturated and monounsaturated types. Tuberculostearic acid is not present. Mycolic acids are present (C_{32}–C_{36}).

Source: infected head of a sheep; habitat is unknown.

DNA G+C content (mol%): not available.

Type strain: S108/98/2, CCUG 39779, CIP 106739, DSM 44611, JCM 12101.

Sequence accession no. (16S rRNA gene): AJ297402.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492247.

18. **Corynebacterium casei** Brennan, Brown, Goodfellow, Ward, Beresford, Simpson, Fox and Cogan 2001, 850[VP]

ca′se.i. L. gen. n. *casei* of cheese, named because the organism was isolated from cheese.

Cells are Gram-stain-positive irregularly shaped rods of 1–3 μm in length. Colonies are cream, circular, matt, entire, low-concave, and 1 mm in diameter. Facultatively anaerobic. Nitrate is reduced to nitrite. Esculin, urea, gelatin, tyrosine, and ONPG are not hydrolyzed. CAMP reaction is negative. Acid is produced from glucose, ribose, mannose, and fructose but not from glycogen, glycerol, erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, methyl-β-xyloside, galactose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, inulin, melezitose, raffinose, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, or 2-ketogluconate. Alkaline and acid phosphatases, esterase, esterase lipase, leucine arylamidase, cystine arylamidase, and pyrazinamidase activities are present. The isolates do not produce lipase, trypsin, chymotrypsin, α-galactosidase, α-mannosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosaminidase.

The cell wall was found to be type IV, containing *meso*-diaminopimelic acid, arabinose, galactose, and short-chain mycolic acids (C_{22}–C_{36}). The menaquinones in the cell wall were of the MK-9(H_2) type. Analysis of the polar lipid of the cell wall revealed the presence of diphosphatidylglycerol, phosphatidylglycerol, phosphotidylinositol, and phosphatidylglycerol mannosides.

Source: surface of smear-ripened cheese.

DNA G+C content (mol%): 51 (HPLC).

Type strain: CIP 107182, DPC 5298, DSM 44701, JCM 12072, LMG S-19264, NCIMB 30130.

Sequence accession no. (16S rRNA gene): AF267152.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) EU616817.

19. **Corynebacterium caspium** Collins, Hoyles, Foster and Falsen 2004, 926[VP]

cas.pi′um. L. neut. adj. *caspium* belonging to the Caspian Sea, referring to the isolation of the type strain from a Caspian seal.

Cells are Gram-stain-positive, irregular-shaped tapered rods and clubs. Nonlipophilic. Colonies are circular, convex, entire, opaque, dull, nonhemolytic and can be moved across the plate while retaining their integrity. Facultatively anaerobic. Nitrate is not reduced. CAMP reaction negative. Acid is produced from D-glucose and D-ribose, but not from glycogen, lactose, maltose, mannitol, sucrose, or D-xylose. Urea is hydrolyzed but esculin and gelatin are not. Activity is detected for esterase, esterase lipase, pyrazinamidase, and trypsin. No activity is detected for acid phosphatase, alkaline phosphatase, chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, lipase, leucine arylamidase, α-mannosidase, pyrrolidonyl arylamidase, phosphoamidase, or valine arylamidase.

Cell-wall murein is based on *meso*-diaminopimelic acid. Corynomycolic acids are not present. Cellular fatty acids are consistent with those described for the genus; tuberculostearic acid is not present.

Source: a Caspian seal; habitat is not known.

DNA G+C content (mol%): not available.

Type strain: M/106/00/5, CCUG 44566, CIP 107965, JCM 13387.

Sequence accession no. (16S rRNA gene): AJ566641.

20. **Corynebacterium ciconiae** Fernández-Garayzábal, Vela, Egido, Hutson, Lanzarot, Fernández-García and Collins 2004, 2194[VP]

ci.co.ni′a.e. L. gen. fem. n. *ciconiae* of a (black) stork.

Cells are Gram-stain-positive rods. Nonlipophilic. Colonies are creamy-white, circular, convex, dry, and nonhemolytic on Columbia blood agar. Facultatively anaerobic. CAMP reaction negative. Nitrate is not reduced. Esculin, urea, and gelatin are not hydrolyzed. Acid is produced from glucose, ribose, glycerol, D-fructose, D-mannose, *N*-acetyl-β-glucosamine, and maltose, but not from D-xylose, mannitol, lactose, sucrose, glycogen, erythritol, L-arabinose, L-xylose, adonitol, methyl β-xyloside, galactose, sorbose, L-rhamnose, dulcitol, inositol, sorbitol, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, arbutin, salicin, cellobiose, melibiose, inulin, melezitose, D-raffinose, xylitol, b-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, D-arabitol, L-arabitol, 2-keto-gluconate, or 5-keto-gluconate. Acidification of D-arabinose, L-fucose, trehalose, starch, and gentiobiose is variable. Activity of alkaline and acid phosphatases, esterase, ester lipase, lipase, leucine arylamidase, phosphoamidase, β-glucosidase, and pyrazinamidase is detected. Pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase,

α-galactosidase, α-fucosidase, chymotrypsin, trypsin, valine arylamidase, and cystine arylamidase are not produced. Mycolic acids are absent. Cellular fatty acids are consistent with those described for the genus.

Source: the trachea of apparently healthy wild nesting black storks (*Ciconia nigra*).

DNA G+C content (mol%): not available.

Type strain: BS13, CCUG 47525, CECT 5779, JCM 13388.

Sequence accession no. (16S rRNA gene): AJ555193.

21. **Corynebacterium confusum** Funke, Osorio, Frei, Riegel and Collins 1998c, 1294[VP]

con.fu′sum. L. past part. *confusum* confused, to indicate that this bacterium might be phenotypically confused with many other *Corynebacterium* species.

Cells are Gram-stain-positive, typically occurring as club-shaped rods as single cells, in pairs, or in small clusters. Colonies are whitish, glistening, convex, and creamy, up to 1.5 mm in diameter after 48 h incubation. Facultatively anaerobic, but weak anaerobic growth. Nonlipophilic. CAMP reaction is negative. Nitrate is reduced. Esculin, urea, and tyrosine are not hydrolyzed. Acid is produced from D-glucose, ribose, D-fructose, tagatose, and 5-ketogluconate, but acid is not produced from maltose, sucrose, mannitol, D-xylose, glycerol, erythritol, arabinose, adonitol, β-methylxyloside, galactose, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, lactose, melibiose, trehalose, inulin, melezitose, D-raffinose, glycogen, xylitol, D-turanose, D-lyxose, fucose, arabitol, gluconate, or 2-ketogluconate. Acid production from β-gentiobiose is variable. Activities of pyrazinamidase, alkaline phosphatase, esterase, and esterase lipase are detected, but pyrrolidonyl arylamidase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not detected. Activities of leucine arylamidase and phosphoamidase are variable.

The cell wall contains *meso*-diaminopimelic acid. Mycolic acids are present. Main straight-chain saturated fatty acids are palmitic and stearic acids; oleic acid is the predominant unsaturated fatty acid. Minor amounts of tuberculostearic acid are present. A clinical strain was CAMP positive, and propionic acid was detected as a metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): not available.

Type strain: CCUG 38267, CIP 105403, DMMZ 2439, DSM 44384, JCM 12102.

Sequence accession no. (16S rRNA gene): Y15886.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492248.

22. **Corynebacterium coyleae** Funke, Pascual Ramos and Collins 1997e, 94[VP]

coy.le′a.e. N.L. gen. fem. n. *coyleae* of Coyle, to honor the American microbiologist Marie B. Coyle for her contributions to the clinical microbiology of coryneform bacteria.

Cells are Gram-stain-positive diphtheroids. Colonies are whitish, circular, convex, and slightly glistening; some colonies have a creamy consistency, and others have a sticky consistency and are ~1 mm after 24 h incubation at 37°C on blood agar. Facultatively anaerobic, but very weak anaerobic growth. Nonlipophilic. Acid is slowly produced from glucose, ribose, D-fructose, D-mannose, and 5-keto-gluconate but not from maltose, sucrose, mannitol, xylose, glycerol, erythritol, D-arabinose, L-arabinose, adonitol, β-methylxyloside, galactose, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, lactose, melibiose, trehalose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, b-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, and 2-keto-gluconate. Nitrate is not reduced. Urea, esculin, casein, tyrosin, and xanthine are not hydrolyzed. The CAMP reaction is strongly positive. Pyrazinamidase, alkaline and acid phosphatases, esterase, esterase lipae, leucine aryamidase, cystine arylamidase, and phosphoamidase activities are detected, but valine arylamidase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are not detected. Pyrrolidonyl arylamidase activity is variable.

The cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): 62–64 (T_m).

Type strain: ATCC 700219, CCUG 38194, CIP 104919, DMMZ 214, DSM 44184, JCM 10381.

Sequence accession no. (16S rRNA gene): X96497.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492250. Six *Corynebacterium coyleae* strains associated with neonatal bacteremias were found to possess *ermX* and express resistance to MLS antibiotics (Fernandez-Natal et al., 2008). By 16S rRNA gene sequencing, *Corynebacterium coyleae* is closely related to (98% identity with) *Corynebacterium mucifaciens* and *Corynebacterium afermentans* but differs from them (~94% identity with) when *rpoB* gene sequences are compared (Khamis et al., 2004) as well as by phenotypic means (Table 32).

23. **Corynebacterium cystitidis** Yanagawa and Honda 1978, 215[AL]

cys.ti′ti.dis. Gr. n. *kustis* bladder; N.L. n. *cystitis* cystitis; N.L. gen. n. *cystitidis* of cystitis.

(This description is largely based on that of Collins and Cummins, 1986.)

Gram-stain-positive rods, 0.5–1.3 µm singly, in pairs often at angles, or in irregular masses. Fimbriae (pili) visible using electron microscopy. Colonies on nutrient agar and serum agar are creamy to pale yellow, entire, circular, opaque, and 1 mm in diameter at 24 h. No hemolysis on various blood agars. Pellicle and granular sediment formed in broth. No growth at 5°C; grows at 41.5°C, and cells remain viable for 30 min at 56°C. Aerobic and facultatively anaerobic. Complex vitamin and amino acid requirements. Positive for glucose, xylose, fructose, maltose, trehalose, dextrin, and

starch; negative for arabinose, rhamnose, galactose, mannose, lactose, sucrose, raffinose, and salicin. Nitrate is not reduced. Urease is produced, hippurate and starch are hydrolyzed, and pyrazinamidase is detected. Tyrosine, esculin, and gelatin are not hydrolyzed; casein is not digested; methyl red, and phosphatase are negative.

Meso-DAP and sugars arabinose and galactose are present. MK-8(H_2) detected.

Source: cows with severe hemorrhagic cystitidis and from the prepuce of healthy bulls.

DNA G+C content (mol%): 52.6–53.9 (T_m).

Type strain: ATCC 29593, CCUG 28794, CIP 103424, DSM 20524, JCM 3715, NBRC 15284, NCTC 11863.

Sequence accession no. (16S rRNA gene): X84252.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492251.

24. **Corynebacterium doosanense** Lee, Cho, Jung, Van Nguyen, Jung, Park, Le and Kim 2009, 2736[VP]

do.o.san.en′se. N.L. neut. adj. *doosanense* belonging to Doosan, named after the Doosan group, a foundation of Chung-Ang University, Seoul, Korea where taxonomic studies on this species were performed.

Gram-stain-positive, nonmotile, nonsporeforming irregular and club-shaped rods that are 0.8~1.0 × 1.0~1.2 µm in size. Colonies are 1~2 mm in diameter, yellow, low convex on GYEA media, and yellow, opaque, low-convex on sheep blood agar after 48 h incubation at 30°C. Aerobic. Activities for sodium pyruvate, pyrazinamidase, ester lipase, leucine arylamidase, and naphthol-AS-BI-phosphohydrolase are detected. Reduction of nitrate and hippurate hydrolysis are positive. No activity is detected for pyrrolidonyl arylamidase, alkaline phosphatase, esterase, lipase, valine arylamidase, cystine arylamidase, trypsin, acid phospatase, α-chymotrypsin, β-glucuronidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, α-mannosidase, α-fucosidase, *N*-acetyl-β-glucosaminidase, leucine aminopeptidase, urease, gelatin, and esculin hydrolysis. Acid production occurs only from glucose.

The cell wall contains *meso*-DAP. Whole cell hydrolysates contain mainly galactose and arabinose. Mycolic acids are detected. Cellular fatty acids are consistent with those described for the genus.

Source: activated sludge, taken from a wastewater treatment plant in Yeongdeuk-gun, Republic of Korea.

DNA G+C content (mol%): 53.5 (T_m).

Type strain: CAU 212, CCUG 57284, KCTC 19568.

Sequence accession no. (16S rRNA gene): EU998655.

25. **Corynebacterium durum** Riegel, Heller, Prévost, Jehl and Monteil 1997a, 1110[VP]

du′rum. L. neut. adj. *durum* hard, tough.

The bacteria are Gram-stain-positive pleomorphic rods which can be long and sometimes filamentous. After aerobic incubation at 37°C for 72 h, colonies are beige, convex, and rough, with convolutions and an irregular margin, and strongly adhere to the agar. Colonies incubated in an aerobic atmosphere supplemented with 10% CO_2 have a dense center and nearly regular margins; they adhere weakly to the agar. Formation of filaments under these conditions is rare. Facultatively anaerobic, but weak anaerobic growth. Nitrate reduction positive, but urea hydrolysis is variable. A weak hydrolysis of esculin can be observed sometimes after at least 72 h of incubation. Gelatin and tyrosine are not degraded. Acid is produced from glucose, maltose, fructose, sucrose, galactose, and mannitol but not from ribose, lactose, trehalose, glycogen, or xylose. Pyrazinamidase is produced, but pyrrolidonyl arylamidase, alkaline phosphatase, β-glucuronidase, β-galactosidase, α-glucosidase, and *N*-acetyl-β-glucosaminidase are not. Propionic acid, but not succinic acid is produced as end product of anaerobic metabolism of glucose.

The cell wall contains *meso*-DAP, with sugars arabinose and galactose. Mycolic acids with short chain lengths (C_{26}–C_{36}) are present (HPLC method). Cellular fatty acids are consistent with those described for the genus (Rassoulian-Barrett et al., 2001).

Source: human respiratory tract specimens and occasionally other normally sterile sites.

DNA G+C content (mol%): 55 (capillary electrophoresis).

Type strain: IBS G15036, CCUG 37331, CIP 105490, DSM 44351, JCM 11948.

Sequence accession no. (16S rRNA gene): Z97069.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492252. *Corynebacterium durum* is the most prominent *Corynebacterium* recovered from throat swabs of healthy adults (von Graevenitz et al., 1998).

26. **Corynebacterium efficiens** Fudou, Jojima, Seto, Yamada, Kimra, Nakamatsu, Hiraishi and Yamanaka 2002, 1130[VP]

ef.fi.ci′ens. L. part. adj. *efficiens* effecting, effective, efficient.

Cells are Gram-stain-positive club-shaped rods 0.8–1.1 × 1.0–4.5 µm in size. Colonies on nutrient agar are smooth, entire, circular, dull to slightly glistening, and generally yellow. Facultatively anaerobic. All strains require biotin for growth. Good growth at 30–40°C; growth occurs up to 45°C. No growth occurs when the pH is below 6 or in the presence of 30% glucose. Nitrate is reduced to nitrite. Hydrolysis of esculin and urea is variable. Acid is formed from glucose, fructose, mannose, ribose, maltose, and dextrin, but not from xylose, mannitol, lactose, salicin, galactose, starch, or glycogen. All strains assimilate acetate, pyruvate, and L-lactate, but they do not assimilate D-lactate, succinate, 2-oxoglutarate, citrate, adipicate, pimelate, glycolate, or glyoxylate. Pyrazinamidase is detected but pyrrolidonyl arylamidase, alkaline phosphatase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, and tyrosinase are not detected. Produces large amounts of L-glutamic acid under aerobic conditions.

The cell wall contains *meso*-DAP. Mycolic acids are present. MK-9(H_2) is the major menaquinone. Cellular fatty acids are consistent with those described for the genus. Polar lipids include phosphatidylinositol and its mannoside.

Source: soil and vegetables.

DNA G+C content (mol%): 59–60.2 (T_m), 63.4 (complete genome sequencing).

Type strain: YS-314, AJ 12310, CCUG 47130, CCUG 48037, DSM 44549, JCM 11189, NBRC 100395.

Sequence accession no. (16S rRNA gene): AB055963.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AP005215. The complete genome of *Corynebacterium efficiens* YS-314^{T}, deposited under GenBank accession no. NC_004369 with 3,147,090 bp, as well as discussion of how amino acid substitutions positively affect thermostability, have been reported (Brune et al., 2005; Nishio et al., 2003).

27. **Corynebacterium falsenii** Sjödén, Funke, Izquierdo, Akervall and Collins 1998, 73^{VP}

fal.se′ni.i. N.L. gen. masc. n. *falsenii* of Falsen, to honor the Swedish microbiologist and taxonomist Enevold Falsen curator of the CCUG, for his lifelong contributions to bacterial taxonomy as well as for the systematic collection and characterization of prokaryotes.

Gram-stain-positive, typically club-shaped rods which appear as single cells, pairs, or in small clusters. Nonlipophilic. Colonies are whitish, circular with entire edges, convex, glistening, of creamy consistency, and start to develop a yellowish pigment after 72 h incubation. Weak anaerobic growth. Acid is produced from glucose, galactose, 5-keto-gluconate, glycerol, ribose, and trehalose, but not from sucrose, mannitol, xylose, adonitol, amygdalin, arabinose, arabitol, arbutin, cellobiose, dulcitol, erythritol, D-fucose, β-gentiobiose, gluconate, 2-keto-gluconate, *N*-acetylglucosamine, methyl α-D-glucoside, glycogen, inositol, inulin, D-lyxose, methyl α-D-mannoside, melezitose, melibiose, D-raffinose, salicin, sorbitol, sorbose, D-turanose, xylitol, and β-methyl-xyloside. Acid production from maltose, fructose, lactose, rhamnose, and D-tagatose is variable. Nitrate is not reduced. Urea hydrolysis is positive but delayed. Esculin, casein, tyrosine, and xanthine are not hydrolyzed. The CAMP reaction is negative. Pyrazinamidase, alkaline and acid phosphatase, esterase, esterase lipase, and phosphoamidase activities are detected, but pyrrolidonyl arylamidase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-glucosidase, *N*-acetylglucosaminidase, α-mannosidase, and α-fucosidase activities are not detected. Lipase, leucine arylamidase, and cystine arylamidase activities are variable.

The cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): not available.

Type strain: Y13024, CCUG 33651, CIP 105466, DSM 44353, JCM 11949.

Sequence accession no. (16S rRNA gene): Y13024.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492253. *Corynebacterium falsenii* was previously known as EF (Enevold Falsen) group 42 bacteria.

28. **Corynebacterium felinum** Collins, Hoyles, Hutson, Foster and Falsen 2001b, 1351^{VP}

fe.li′num. L. neut. adj. *felinum* pertaining to cats.

Cells are Gram-stain-positive diphtheroids. Colonies are nonhemolytic. Facultatively anaerobic. Nonlipophilic. Acid is produced from glucose, maltose, and ribose but not from lactose, mannitol, sucrose, *N*-acetyl-β-glucosamine, and D-xylose. Activity is detected for α-glucosidase, pyrazinamidase, pyrrolidonyl arylamidase, and leucine arylamidase. No activity is observed for alkaline and acid phosphatases, chymotrypsin, esterase, ester lipase, lipase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, α-fucosidase, α-mannosidase, phosphoamidase, valine arylamidase, and trypsin. Nitrate is not reduced. Esculin, urea, and gelatin are not hydrolyzed.

The cell wall contains *meso*-DAP. Mycolic acids (C_{32}–C_{36}) detected. MK-8(H_2) is the predominant menaquinone. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present.

Source: a dead Scottish wild cat (*Felis sylvestris*); habitat is unknown.

DNA G+C content (mol%): not available.

Type strain: M714/95/5, CCUG 39943, CIP 106740, DSM 44508, JCM 12103.

Sequence accession no. (16S rRNA gene): AJ401282.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492254.

29. **Corynebacterium flavescens** Barksdale, Lanéelle, Pollice, Asselineau, Welby and Norgard 1979, 222^{AL} (*Microbacterium flavum* Orla-Jensen 1919, 181)

fla.ves′cens. L. v. *flavescere* to become yellow; L. part. adj. *flavescens* becoming yellow.

(This description is largely based on that of Collins and Cummins, 1986.)

Gram-stain-positive to Gram-stain-variable pleomorphic rods, often with tapered ends, showing metachromatic granules. Growth is yellow on Loeffler's agar; on BHI agar, colonies are smooth, butyrous, and cream-colored. Colonies on tellurite agar are grayish black, later developing grayish white centers. Aerobic and facultatively anaerobic. Complex nutritional requirements.

Glucose, fructose, galactose, mannose, and methyl red are positive. Negative for arabinose, xylose, rhamnose, lactose, maltose, sucrose, trehalose, raffinose, salicin, dextrin, and starch fermentation. Hippurate and gelatin hydrolysis negative. Nitrate not reduced, urease not detected, and pyrazinamidase negative. Reactions for esculin, tyrosine, and casein hydrolysis unknown.

Information regarding DAP species, menaquinones, presence of mycolates unknown. Cellular fatty acids are consistent with those of the genus (Bernard et al., 1991).

Source: dairy products.

DNA G+C content (mol%): 58.3 (T_m).

Type strain: 8 of Orla-Jensen, ATCC 10340, CCUG 28791, CIP 69.5, DSM 20296, JCM 1317, LMG 4046, NBRC 14136, NCCB 42012, NCIMB 8707, VKM Ac-1956.

Sequence accession no. (16S rRNA gene): X84441.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492255.

30. **Corynebacterium freiburgense** Funke, Frodl, Bernard and Englert 2009, 2056^{VP}

frei.bur.gen′se. N.L. neut. adj. *freiburgense* from Freiburg/Breisgau, Germany, named after the city where the bacterium was first isolated.

Gram-stain-positive typically club-shaped rods that occur as single cells, in pairs, or in small clusters. Colonies are beige-whitish, dryish, with irregular edges, adherent to agar, convoluted, and up to 1–2 mm in diameter after 48 h. In 5-d-old colonies, a "spoke-wheel" macroscopic morphology may be observed. Facultatively anaerobic, but anaerobic growth is weak. Nonlipophilic. Acid is produced from glucose, maltose, sucrose, fructose, galactose, 5-keto-gluconate, lactose, mannose, ribose, and tagatose, but acid is not produced from *N*-acetylglucosamine, adonitol, amygdalin, arabinose, arabitol, arbutin, cellobiose, dulcitol, erythritol, fucose, gentiobiose, gluconate, glycerol, inositol, inulin, 2-keto-gluconate, lyxose, mannitol, melezitose, melibiose, methyl-α-D-glucoside, methyl-α-D-mannoside, β-methyl-xyloside, D-raffinose, rhamnose, salicin, sorbitol, sorbose, starch, trehalose, D-turanose, xylitol, and xylose. Activity of the following enzymes can be detected: nitrate reductase, β-galactosidase, β-glucosidase, esterase, esterase lipase, leucine arylamidase, cystine arylamidase, acid phosphatase, and phosphoamidase. Activities of pyrazinamidase, urease, pyrrolidonyl arylamidase, gelatinase, lipase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-glucuronidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not detected. The CAMP reaction is negative.

The cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus.

Source: a patient's wound after a dog bite.

DNA G+C content (mol%): not available.

Type strain: 1045, CCUG 56874, DSM 45254.

Sequence accession no. (16S rRNA gene): FJ157329.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) GQ913437.

31. **Corynebacterium freneyi** (Renaud, Aubel, Riegel, Meugnier and Bollet 2001) emend. Funke and Frodl 2008a, 1515 (Effective publication: Funke and Frodl 2008a, 642.)

fre′ney.i. N.L. gen. masc. n. *freneyi* of Freney, to honor the French microbiologist Jean Freney.

Gram-stain-positive typically club-shaped rods. Colonies are whitish-grayish, but a minority of strains is yellowish, dry, rough, with a distinct wrinkled morphology and irregular edges. Colonies are 1–2 mm in diameter after 48 h of incubation on blood agar. Nonlipophilic. Fermentative metabolism. Reduction of nitrates is variable. The strains express α-glucosidase, pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, leucine arylamidase (20 of 21 strains), and phosphoamidase. They do not produce pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, *N*-acetyl-β-glucosaminidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, α-mannosidase, or α-fucosidase. The strains do not hydrolyze esculin, gelatin, or urea. The CAMP reaction is negative. Produces acid from glucose, maltose, sucrose, galactose (20 of 21 strains), D-fructose, D-mannose, trehalose, D-turanose, and 5-keto-gluconate. Ribose and D-tagatose acidifications are slow and weak. The results of fermentation of lactose and glycogen are variable, and very few strains (2 of 21) ferment mannitol. Xylose, glycerol, erythritol, D-arabinose, and 2-keto-gluconate are not fermented. Glucose is also fermented at 42°C, and strains may grow at 20°C.

The cell wall contains *meso*-DAP, sugars arabinose and galactose, and mycolic acids. Cellular fatty acids are consistent with those described for the genus.

Source: human clinical specimens.

DNA G+C content (mol%): not available.

Type strain: CCUG 45704, CIP 106767, DSM 44506, ISPB 6695110, JCM 12104.

Sequence accession no. (16S rRNA gene): AJ292762.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492237. Some strains are resistant to erythromycin, clindamycin, penicillin, and cefotaxime. *Corynebacterium freneyi* cannot be easily discerned from *Corynebacterium xerosis* and *Corynebacterium hansenii* by 16S rRNA, *rpoB*, or 16S–23S spacer region gene sequence analyses; these are best separated by DNA–DNA hybridization or phenotypic means.

32. **Corynebacterium glaucum** Yassin, Kroppenstedt and Ludwig 2003, 707[VP]

glau′cum. L. neut. adj. *glaucum* bluish, light-gray, pertaining to the appearance of colonies.

Cells are Gram-stain-positive, dumbbell-shaped (when examined after 18 h growth), or showing typical coryneform morphology (when examined after 1 week of growth). On Columbia blood agar supplemented with 5% sheep blood, BHI agar and trypticase soy agar, colonies are light-gray in color. Facultatively anaerobic. Nitrate is not reduced. Hydrolyzes hippurate but not esculin, urea, gelatin, and starch. Produces acid from glucose and sucrose but not from arabinose, cellobiose, glycerol, glycogen, inulin, lactose, maltose, mannitol, raffinose, rhamnose, ribose, salicin, sorbitol, trehalose, and xylose. Displays alkaline phosphatase, pyrazinamidase, ester lipase, leucine arylamidase, and phosphoamidase activities but is negative for acid phosphatase, arginine dihydrolase, cystine arylamidase, esterase, lipase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, pyrrolidonyl arylamidase, valine arylamidase, trypsin, and chymotrypsin. Acetoin production is positive, but indole production is negative. Produces lactate but not propionate as the major product of glucose fermentation.

Contains *meso*-DAP in addition to sugars galactose and arabinose (i.e. cell-wall chemotype IV). Contains corynemycolic acids, and fatty acid profile contains saturated and unsaturated fatty acids. Tuberculostearic acid is absent. Contains MK-7(H_2), MK-8(H_2), and MK-9(H_2) as respiratory menaquinones, with MK-8(H_2) as the major component. Phospholipid pattern type PI, with no nitrogen-containing compounds.

Source: a cosmetic dye.

DNA G+C content (mol%): 64.3 (HPLC).

Type strain: IMMIB R-5091, DSM 44530, JCM 12208, NRRL B-24142.

Sequence accession no. (16S rRNA gene): AJ431634.

33. **Corynebacterium glucuronolyticum** Funke, Bernard, Bucher, Pfyffer and Collins 1995b, 879[VP] (Effective publication: Funke, Bernard, Bucher, Pfyffer and Collins 1995a, 214.)

glu.cu.ro.no.ly'ti.cum. N.L. n. *acidum glucuronicum* glucuronic acid; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *glucuronolyticum* cleaving β-glucuronic acid.

Gram-stain-positive coryneforms, about 1–3 µm in length. Colonies are white-yellowish, circular, convex, and nonhemolytic on sheep blood agar. Colonies are 1–1.5 mm after 24 h of incubation in 5% CO_2 on blood agar. Nonlipophilic. Facultatively anaerobic. Acid is produced from glucose and sucrose; some strains produce acid from maltose, xylose, and ribose. Acid is not produced from mannitol and glycogen. Pyrazinamidase, esterase, esterase lipase, leucine arylamidase, cystine arylamidase, acid phosphatase, and, β-glucuronidase are present; some strains exhibit activity of alkaline phosphatase, phosphoamidase, α-glucosidase, and β-glucosidase. Hydrolysis of urea and esculin are variable. Some strains reduce nitrate.

Cellular fatty acids are consistent with those described for the genus.

Source: genitourinary specimens of human males, but can also be isolated from the urogenital tract of pigs (Devriese et al., 2000) or human body fluids that are normally sterile (Bernard et al., 2002).

DNA G+C content (mol%): 52–58 (HPLC).

Type strain: 6, ATCC 51860, CCUG 35055, CIP 104577, DMMZ 838, DSM 44120, JCM 11612, LMG 19047.

Sequence accession no. (16S rRNA gene): X86688.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492256. *Corynebacterium glucuronolyticum* strains may be resistant to erythromycin, clindamycin, and tetracycline (Funke et al., 1996b). *Corynebacterium seminale* (Riegel et al., 1996b) (Effective publication: Riegel et al. 1995d.) is deemed to be a later heterotypic synonym of *Corynebacterium glucuronolyticum* (Devriese et al., 2000). The DNA G+C content (mol%) of *Corynebacterium seminale* was found to be 60% (capillary electrophoresis method), but that of *Corynebacterium glucuronolyticum* sp. nov. was not extant in 1995. *Corynebacterium seminale* type strain has been curated under ATCC 51866, CCUG 34780, CCUG 34888, CIP 104297, DSM 44288, IBS B12915, JCM 10394, with GenBank accession number *(16S rRNA gene)* X84375.

34. **Corynebacterium glutamicum** (Kinoshita, Nakayama and Akita 1958) Abe, Takayama and Kinoshita 1967, 299[AL] (*Micrococcus glutamicus* Kinoshita, Nakayama and Akita 1958, 176)

glu.ta'mi.c.um. N.L. neut. adj. *glutamicum* pertaining to glutamic acid.

(This description is largely based on that of Collins and Cummins, 1986.)

Short Gram-stain-positive rods or ellipsoids 0.7–1.0 × 1.0–3.0 µm, occurring singly, in pairs, or in irregular masses. In lag phase cultures, quite long branching cells, but in mid- to late exponential phase cultures the cells are very short, ellipsoidal to almost coccal. Colonies on nutrient agar are smooth, entire, circular, dull to slightly glistening, and generally pale yellow to yellow. Gray to black colonies on tellurite agar. Moderate turbidity with floccular sediment in broth. Optimal growth at 25–37°C, with only slight growth at 42°C. Aerobic and facultatively anaerobic. Glucose, fructose, mannose, maltose, sucrose, trehalose, and methyl red positive. Negative for arabinose, xylose, rhamnose, galactose, lactose, raffinose, salicin, dextrin, and starch fermentation. Hippurate hydrolyzed, urease is produced, but gelatin is negative. Nitrate is reduced but phosphatase and pyrazinamidase negative. Esculin and casein negative.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose. Mycolates are present. MK-9(H_2) is the major menaquinone. Cellular fatty acids consistent with those of the genus. All strains produce large amounts of L-glutamic acid under aerobic conditions.

Source: sewage.

DNA G+C content (mol%): 55–57.7 (T_m), 53.8 (complete genome sequencing) (Ikeda and Nakagawa, 2003; Kalinowski et al., 2003).

Type strain: ATCC 13032, CCUG 27702, CIP 82.8, DSM 20300, HAMBI 2052, JCM 1318, LMG 3730, NBRC 12168, NRRL B-2784.

Sequence accession no. (16S rRNA gene): AF314192.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) NC_003450. *Brevibacterium divaricatum* Su and Yamada 1960[AL], *Corynebacterium lilium* Lee and Good 1963, 1349[AL], "*Brevibacterium flavum*" DSM 20411, and "*Brevibacterium lactofermentum*" DSM 20412 and DSM 1412 are all considered as later heterotypic synonyms of *Corynebacterium glutamicum* (Liebl et al., 1991). Complete genome sequence of *Corynebacterium glutamicum* ATCC 13032[T] was deposited under GenBank accession no. NC_006958 with 3,282,708 bp, from which various transcriptional functions were conjectured (Brune et al., 2005; Kalinowski et al., 2003). Concurrently, a second genome sequencing project of the same strain, deposited under GenBank accession no. NC_004350, was described as having 3,309,401 bp (Ikeda and Nakagawa, 2003).

35. **Corynebacterium halotolerans** Chen, Li, Tang, Kroppenstedt, Stackebrandt, Xu and Jiang 2004, 781[VP]

ha.lo.to'le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating; N.L. pres. part. *halotolerans* referring to the ability to tolerate high salt concentrations.

Gram-stain-positive diphtheroid and irregular rods. Colonies on modified ISP 5 medium, trypticase/soy agar medium, and Mueller–Hinton agar medium are moderately yellow, circular, entire, somewhat convex, and opaque after 24 h at 28°C. Optimum growth temperature is 28°C. Obligately aerobic. Nonlipophilic. Optimum gowth concentration of KCl, NaCl, and $MgCl_2{\cdot}6H_2O$ is 10%. Positive for nitrate reduction, but negative for milk peptonization and coagulation, gelatin liquefaction, growth in cellulose, production of H_2S and melanin, starch hydrolysis, and urease production. Activities for lipase and β-glucuronidase are positive. Ornithine decarboxylase, arginine dihydrolase, lysine decarboxylase, α- and β-galactosidase, *N*-acetyl-β-glucosaminidase, and β-glucosidase activities are negative. The following substrates are utilized: glucose, galactose, sucrose, arabinose, mannose, mannitol, maltose, starch, xylose, ribose, salicin, and dextrin. Cellobiose, fructose, amygdalin, and lactose are not utilized. Acid production occurs only from glucose.

The cell wall contains *meso*-DAP with sugars mainly galactose and arabinose. Menaquinones are MK-8(H_2) (35.5%)

and MK-9(H_2) (64.5%); phospholipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, glycolipid, and phosphatidylinositol mannosides. Cellular fatty acids are consistent with those described for the genus, with significant quantities (7.4% of total) TBSA detected. Predominant mycolic acids include $C_{32:0}$ (36.0%), $C_{34:0}$ (20.8%), $C_{34:1}$ (25.1%), $C_{36:0}$ (3.6%), $C_{36:1}$ (8.4%), and $C_{36:2}$ (5.1%).

Source: saline soil collected in Xinjiang Province, west China.

DNA G+C content (mol%): 63 (T_m).

Type strain: YIM 70093, CCTCC AA 001024, DSM 44683, JCM 12676.

Sequence accession no. (16S rRNA gene): AY226509.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EU004065.

36. **Corynebacterium hansenii** Renaud, Le Coustumier, Wilhem, Aubel, Riegel, Bollet and Freney 2007, 1115[VP]

han.sen′i.i. N.L. gen. *masc.* n. *hansenii* of Hansen, to honor the Belgian microbiologist Willy Hansen.

Gram-stain-positive, typically club-shaped rods. Colonies are yellow-pigmented, dry, rough, and with irregular edges, roughly 0.5–1.0 mm in diameter. Nonlipophilic. Facultatively anaerobic. Produces acid from glucose, ribose, maltose, and sucrose. Does not reduce nitrates. No hydrolysis of esculin, urea, or gelatin. Pyrazinamidase positive. Does not produce alkaline phsophatase, pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, or *N*-acetyl-β-glucosaminidase. D-Ribose, D-galactose, D-glucose, and D-fructose are used as carbon substrates, but D-maltose and D-turanose are not. Glucose is not fermented at 42°C but growth will occur at 20°C.

Source: human liposarcoma pus; the pathogenic role is not known.

DNA G+C content (mol%): not available.

Type strain: C-138, CCUG 53252, CIP 108444, DSM 45109, JCM 15293.

Sequence accession no. (16S rRNA gene): AM946639.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) AY684044 and FJ268580. *Corynebacterium hansenii* cannot be easily discerned from *Corynebacterium xerosis* and *Corynebacterium freneyi* by 16S rRNA, *rpoB*, or 16S–23S spacer region gene sequence analyses; these are best separated by DNA–DNA hybridization or phenotypic means.

37. **Corynebacterium imitans** Funke, Efstratiou, Kuklinska, Hutson, De Zoysa, Engler and Collins, 1997a, 1274 (Effective publication: Funke, Efstratiou, Kuklinska, Hutson, De Zoysa, Engler and Collins 1997b, 1982.)

i′mi.tans. L. part. adj. *imitans* imitating, copying, indicating that this bacterium was isolated from patients with an illness that was imitating the clinical picture of pharyngeal diphtheria and also indicating that the biochemical profile of the newly described bacterium imitates the biochemical profiles of other *Corynebacterium* species.

Gram-stain-positive diphtheroids. Nonlipophilic. Colonies are white-grayish, glistening, circular, convex, creamy, and have entire edges. Acid is produced from D-arabinose, ribose, D-glucose, D-fructose, D-mannose, maltose, lactose, and L-fucose and weakly from sucrose but not from glycerol, erythritol, L-arabinose, xylose, adonitol, β-methyl-xyloside, galactose, L-sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α-methyl-mannoside, α-methyl-glucoside, *N*-acetyl-glucosamine, amygdalin, arbutin, salicin, cellobiose, melibiose, trehalose, inulin, melezitose, D-raffinose, glycogen, xylitol, b-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, D-arabitol, L-arabitol, gluconate, and 2-keto-gluconate. Nitrate reduction is variable (Funke, unpublished). Urea, esculin, and tyrosine are not hydrolyzed. The CAMP reaction is positive. Pyrazinamidase (weak), alkaline phosphatase, esterase, esterase lipase, acid phosphatase, and phosphoamidase activities are detected, but lipase, pyrrolidonyl arylamidase, leucine arylamidase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are not detected.

Meso-DAP and mycolic acids are present. Cellular fatty acids are consistent with those described for the genus. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): 62 (T_m).

Type strain: ATCC 700354, CCUG 36877, CIP 105130, DSM 44264, IFO (now NBRC) 16163, JCM 10386, NBRC 100416, NCTC 13015.

Sequence accession no. (16S rRNA gene): Y09044.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492259.

38. **Corynebacterium jeikeium** Jackman, Pitcher, Pelczynska and Borman 1988, 136[VP] (Effective publication: Jackman, Pitcher, Pelczynska and Borman 1987, 88.)

jei.kei′um. N.L. neut. adj. *jeikeium* formed from the initial letters of the surnames of W. D. Johnson and D. Kaye, doctors who described infections attributed to the taxon in 1970.

Gram-stain-positive rods, ~0.5 × 2 μm, pleomorphic, occasionally club-shaped, arranged in V-forms or palisades. Cells contain metachromatic granules. Colonies are small (1–2 mm), entire, grayish-white, and nonhemolytic. Obligate aerobic. Lipophilic. Good growth occurs at 30–42°C but poorly at 22°C. Grows on 0.03% tellurite agar and bile salt agar, hydrolyzes Tweens 20 and 80 but not Tweens 40 and 60. Acid is produced from glucose and galactose; some strains produce acid from maltose. Acid is not produced from adonitol, arabinose, cellobiose, dulcitol, dextrin, erythritol, fructose, glycerol, glycogen, inositol, lactose, mannitol, mannose, melibiose, raffinose, rhamnose, salicin, sorbose, sucrose, and trehalose. Methyl red test negative; nitrate is not reduced. H_2S, acetoin, and indole are not produced. Tyrosine, casein, gelatin, and urea are not degraded. Citrate is not utilized. Esculin and starch are not hydrolyzed, gluconate is not converted to 2-ketogluconate. Arginine dihydrolase, and lysine and ornithine decarboxylase tests are negative.

Cell wall contains *meso*-DAP and sugars arabinose and galactose. Mycolic acids are present and are principally of carbon-chain length C_{32}–C_{36}. Cellular fatty acids are con-

sistent with those described for the genus with only trace amounts of 10-methyl-octadecanoic acid (tuberculostearic acid) occurring. Does not produce propionic acid as metabolic product (Bernard et al., 2002).

Source: human body surfaces and human clinical specimens.

DNA G+C content (mol%): 58–61 (T_m).

Type strain: ATCC 43734, CCUG 27192, CIP 103337, DSM 7171, JCM 9384, NCTC 11913.

Sequence accession no. (16S rRNA gene): X84250.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492231.

Corynebacterium jeikeium Jackman et al. 1988 was previously known as CDC coryneform group JK. Four genomospecies among *Corynebacterium jeikeium* strains have been described (Riegel et al., 1994b). *Corynebacterium jeikeium* strains are often multidrug-resistant (Riegel et al., 1996a; Sanchez et al., 2003). The complete genome of *Corynebacterium jeikeium* strain K411 deposited under GenBank accession no. CR931997 has 2,462,499 bp (Tauch et al., 2005).

39. **Corynebacterium kroppenstedtii** Collins, Falsen, Åkervall, Sjödén and Alvarez 1998, 1453[VP]

krop.pen.sted′ti.i. N.L. gen. masc. n. *kroppenstedtii* of Kroppenstedt, to honor the German microbiologist Reiner M. Kroppenstedt for his many contributions to the microbiology of actinomycetes.

Gram-stain-positive diphtheroids that occur as single cells or are arranged in V-shaped forms or palisades. Colonies on blood agar are nonpigmented, small (<0.5 in diameter after 24 h incubation), smooth, convex, and nonhemolytic. Facultatively anaerobic. Grows in 10% NaCl and at 42°C. Nitrate is not reduced to nitrite. Esculin is hydrolyzed but urea and gelatin are not. Acid is produced from glucose, maltose (weak reaction), and sucrose. Acid is not produced from lactose, ribose, D-xylose, mannitol, and glycogen. Leucine arylamidase, esterase, esterase lipase, and pyrazinamidase are produced. Alkaline and acid phosphatases, *N*-acetyl-β-glucosaminidase, cystine arylamidase, chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, lipase, α-mannosidase, pyrrolidonyl arylamidase, trypsin, and valine arylamidase are not detected.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose Cellular fatty acids are consistent with those described for the genus, with tuberculostearic acid being detected. Mycolic acids are not present. Some clinical isolates produce propionic acid as a metabolic product (Bernard et al., 2002).

Source: human clinical specimens, in particular, in cases of lobular granulomatous mastitis (Kieffer et al., 2006; Paviour et al., 2002; Riegel et al., 2004).

DNA G+C content (mol%): 62 (T_m).

Type strain: CCUG 35717, CIP 105744, DSM 44385, JCM 11950.

Sequence accession no. (16S rRNA gene): Y10077.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492274. Although *Corynebacterium kroppenstedtii* was not described as being lipophilic by Collins et al., this feature has been observed by other authors (Riegel et al., 2004; Tauch et al., 2008a). The complete genome of DSM 44385[T], with 2,446,804 bp, has been deposited under GenBank accession no. NC_012704 (Tauch et al., 2008a).

40. **Corynebacterium kutscheri** (Migula 1900) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 395[AL] (*Bacterium kutscheri* Migula 1900, 372)

kut′sche.ri. N.L. gen. masc. n. *kutscheri* of Kutscher, the bacteriologist who first isolated the species.

(This description is largely based on that of Collins and Cummins, 1986.)

Irregularly staining slender rods, often clubbed, sometimes with pointed ends; metachromatic granules present. Large numbers of fimbriae present. Small, thin, yellowish or grayish white serrate colonies on nutrient agar. Facultatively anaerobic. Reduces potassium tellurite. Positive for glucose, fructose, mannose, maltose, sucrose, salicin, dextrin, and starch; negative for arabinose, xylose, rhamnose, galactose, lactose, and raffinose. Trehalose variable. Nitrate is reduced, urease is produced, hippurate is hydrolyzed and pyrazinamidase is detected. Tyrosine, esculin, and gelatin are not hydrolyzed; casein is not digested; methyl red and phosphatase are negative.

Cell wall contains *meso*-DAP and the sugars arabinose, galactose, mannose, and rhamnose. This species appears to be the only organism in the genus *Corynebacterium* which may have rhamnose as a cell-wall sugar in addition to arabinose and galactose. Metabolic products include propionate and lactate, with lesser amounts of acetate, pyruvate, and oxalacetate.

Source: a frequent parasite of mice and rats, but also occurs in other small rodents such as voles. An infection in a human has been reported after the patient had been bitten by a rat (Holmes and Korman, 2007).

DNA G+C content (mol%): ~46 (T_m).

Type strain: ATCC 15677, CCUG 27535, CIP 103423, DSM 20755, JCM 9385, NBRC 15288, NCTC 11138.

Sequence accession no. (16S rRNA gene): X81871.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492257.

41. **Corynebacterium lipophiloflavum** Funke, Hutson, Hilleringmann, Heizmann and Collins 1997a, 1274[VP] (Effective publication: Funke, Hutson, Hilleringmann, Heizmann and Collins 1997c, 223.)

li.po.phi.lo.fla′vum. Gr. n. *lipos* fat; Gr. neut. adj. *philon* loving; L. adj. *flavus -a -um* yellow; N.L. neut. adj. *lipophiloflavum* fat loving and yellow.

Gram-stain-positive club-shaped rods, 1–3 μm in length. Slightly lipophilic. Colonies are yellowish, circular, convex, and slightly dry; tiny colonies (0.2 mm in diameter) after 24 h incubation on blood agar, but ~1 mm if grown on blood agar enriched with 1% Tween 80. Acid is not produced from glucose, maltose, sucrose, mannitol, xylose, lactose, and glycogen. Nitrate is not reduced. Urea is slowly hydrolyzed, but esculin is not hydrolyzed. The CAMP reaction is negative. Pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, lipase, leucine arylamidase, acid phosphatase, and phosphoamidase activities are detected but pyrrolidonyl arylamidase, valine arylamidase, cystine arylamidase,

trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are not detected.

Cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus.

Source: human clinical specimens.

DNA G+C content (mol%): 65 (T_m).

Type strain: ATCC 700352, CCUG 37336, CIP 105127, DMMZ 1944, DSM 44291, JCM 10383.

Sequence accession no. (16S rRNA gene): Y09045.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492260.

42. **Corynebacterium lubricantis** Kämpfer, Lodders, Warfolomeow, Falsen and Busse 2009, 1114[VP]

lu.bri.can′tis. L. v. *lubricare* to lubricate; N.L. *lubricans – antis* (from L. part. adj. *lubricans*); N.L. gen. n. *lubricantis* of/from a (coolant) lubricant.

Gram-stain-positive rods ~1 µm long, with yellow, shiny, translucent colonies 0.5 mm in diameter after 24 h. Grows from 10–45°C but most testing was done at 28°C. Unique, as this species can grow on MacConkey agar. The following compounds are used as sole sources of carbon: D-fructose, D-glucose, acetate, fumarate, and DL-lactate; the following compounds are not utilized: *N*-acetylgalactosamine, *N*-acetylglucosamine, L-arabinose, L-arbutin, cellobiose, D-galactose, maltose, D-mannose, L-rhamnose, D-ribose, salicin, trehalose, D-xylose, adipate, 2-oxoglutarate, D-gluconate, melibiose, sucrose, adonitol, *myo*-inositol, maltitol, D-mannitol, D-sorbitol, propionate, *cis*- and *trans*-aconitate, 4-aminobutyrate, citrate, glutarate, DL-3-hydroxybutyrate, itaconate, L-malate, mesaconate, pyruvate, L-alanine, D-alanine, L-aspartate, L-leucine, L-ornithine, L-proline, L-serine, putrescine, azelate, suberate, L-histidine, L-phenylalanine, L-serine, L-tryptophan, 3-hydroxybenzoate, and phenylacetate. Acid is produced from glucose and trehalose. No acids are produced from sucrose, D-mannitol, dulcitol, lactose, rhamnose, maltose, galactose, salicin, adonitol, inositol, sorbitol, L-arabinose, raffinose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, erythritol, melibiose, D-arabitol, or D-mannose. *p*-Nitrophenyl (pNP)-β-D-glucopyranoside, *p*-NP-β-D-glucuronide, bis-*p*-NP-phosphate, and bis-*p*-NP-phenylphosphonate are hydrolyzed. The following compounds are not hydrolyzed: *p*-NP-α-D-glucopyranoside, *p*-NP-β-D-galactopyranoside, *p*-NP-β-D-xylopyranoside, bis- *p*-NP-phosphorylcholine, L-alanine-*p*-nitroanilide (pNA), L-proline pNA, and C-L-glutamate pNA.

Chemotaxonomic properties as described for genus except that in addition to MK-9(H_2) and MK-8(H_2), MK-7(H_2), is also detected. The lipid profile consists of the major compounds phosphatidylglycerol and an unknown glycolipid, moderate amounts of phosphatidylinositol, diphosphatidylglycerol, two unknown glycolipids, three unknown aminolipids and an unknown polar lipid, and minor amounts of two glycolipids, an aminolipid and a polar lipid. Polyamines are present in small amounts; the major compounds are spermidine and spermine. The characteristic peptidoglycan diamino acid is *meso*-DAP. Testing for corynemycolates was not done. Cellular fatty acids are consistent with those described for the genus except that significant (11–31% of total vol.) of tuberculostearic acid is detected.

Source: coolant lubricant.

DNA G+C content (mol%): 66.6 (HPLC).

Type strain: KSS-3Se, CCM 7546, CCUG 56567, DSM 45231, JCM 16607.

Sequence accession no. (16S rRNA gene): FM173119.

43. **Corynebacterium macginleyi** Riegel, Ruimy, De Briel, Prévost, Jehl, Christen and Monteil 1995e, 132[VP]

mac.gin′ley.i. N.L. gen. masc. n. *macginleyi* of McGinley, named in honor of Kenneth John McGinley who made important contributions to the knowledge of lipid-requiring diphtheroids.

Gram-stain-positive pleomorphic rods occasionally with metachromatic granules, arranged in palisades or V-shaped forms. Facultatively anaerobic. Strains are lipophilic in that no growth is seen in brain heart infusion broth after 72 h at 37°C, but growth is visible after 24 h in the same broth supplemented with 0.01–1% Tween 80. Very small (less than 1 mm in diameter) and non-β-hemolytic colonies appear after 48 h on sheep blood agar, but on 1% Tween 80-supplemented sheep blood agar reddish-beige colonies are larger (2–4 mm in diameter) and Tween esterase activity is noted. Nitrate is reduced to nitrite. Acid is produced from D-glucose, ribose, and sucrose but not from maltose, lactose, D-xylose, trehalose, or glycogen. Fermentation of D-mannitol occurs variably. Tyrosine, gelatin, starch, and urea are not degraded or hydrolyzed. Esculin is not hydrolyzed. DNA is degraded. Hydrolysis of hippurate is variable. Arginine is not degraded. Cells produce alkaline phosphatase, but pyrazinamidase, pyrrolidonyl, arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, and *N*-acetyl-β-glucosaminidase are not produced.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose. Mycolic acids of short chain lengths (C_{26}–C_{36}) are present cellular fatty acid composition consistent with those of the genus, but tuberculostearic acid was not detected. Propionic acid is not detected as metabolic product (Bernard et al., 2002).

Source: predominately recovered from human eye specimens, particularly the conjunctiva (Funke et al., 1998d; Joussen et al., 2000) and from a case of endophthalmitis (Ferrer et al., 2004).

DNA G+C content (mol%): 58 (HPLC).

Type strain: JCL-2, ATCC 51787, CCUG 32361, CIP 104099, DSM 44284, JCM 11684.

Sequence accession no. (16S rRNA gene): AJ439345, X80499.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492276. *Corynebacterium macginleyi* Riegel et al. 1995d was previously known as CDC coryneform group G-1, the nitrate reducing form of CDC coryneform group G as well as a lipid-requiring diphtheroid, genomospecies II. Opportunistic infections in humans by *Corynebacterium macginleyi* associated with other sites have been described, including intravenous catheter-related infections (Dobler and Braveny, 2003; Villanueva et al., 2002) and endocarditis (Pubill Sucarrat et al., 2003). An outbreak involving quinolone-resistant strains has been reported (Eguchi et al., 2008). *rpoB* Gene sequencing

should be done to differentiate strains from *Corynebacterium accolens*, as these species can not be easily distinguished by 16S rRNA gene sequencing.

44. **Corynebacterium marinum** Du, Jordan, Rooney, Chen and Austin 2010, 1946[VP]

ma.ri′num. L. neut. adj. *marinum* of the sea, marine.

Cells are short Gram-stain-positive diphtheroid rods; some of the cells are arranged in a V formation. Colonies on Marine 2216E agar medium are circular, erose, convex, yellow, of a creamy consistency, and ~0.5–1.5 mm after 48 h at 28°C. Facultatively anaerobic; methyl red negative. Voges–Proskauer positive, nitrate is reduced, and horse blood cells are lyzed. Esculin and urea are not hydrolyzed, but casein is digested, and starch and pullulan are hydrolyzed. Gelatin is not liquefied. Tween 20–80 are hydrolyzed. Cells grow in the presence of 0–8% (w/v) NaCl and at 4–37°C. Prolific growth occurs at 30–32°C in media that contains 1% (w/v) NaCl. Using the API 50CH system, esculin ferric, citrate, salicin, D-maltose, and glycogen are utilized. Acid is produced from glucose, maltose, sucrose, and glycogen, but not from ribose, xylose, mannitol, or lactose. Esterase lipase, leucine arylamidase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, pyrazinamidase, and β-glucuronidase are positive. Esterase, lipase, valine arylamidase, cystine arylamidase, trypsin, alkaline phosphatase, pyrrolidonyl arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are negative. The antibiotic susceptibility of the isolate was tested using antimicrobial discs. The type strain is resistant to nalidixic acid (30 μg), nitrofurantoin (50 μg), sulfamethizole (200 μg), tetracycline (100 μg), and cotrimoxazole (25 μg), but sensitive to ampicillin (25 μg), chloramphenicol (50 μg), gentamicin (10 μg), kanamycin (30 μg), carbenicillin 143 (100 μg), and streptomycin (25 μg).

Cellular fatty acid composition is consistent with those of the genus. Detection of corynemycolates and other chemotaxonomic information not described.

Source: coastal sediment close to a coal-fired power station in Qingdao, China.

DNA G+C content (mol%): 65.0 (HPLC).

Type strain: D7015, CGMCC 1.6998, NRRL B-24779.

Sequence accession no. (16S rRNA gene): DQ219354.

45. **Corynebacterium maris** Ben-Dov, Ben Yosef, Pavlov and Kushmaro 2009, 2461[VP]

ma′ris. L. gen. n. *maris* of the sea.

Gram-stain-positive coccobacilli approximately 0.5–0.8 μm × 0.8–1.5 μm. Nonhemolytic. Forms small colonies (approximately 1 mm and 2.5 mm in diameter after 48 and 72 h, respectively) after incubation at 30°C. Colonies are yellowish to yellow, circular, convex, smooth, and opaque. Grows well at 0.5–4.0% salinity, at pH 7.2–9.0, and at 30–37°C. Aerobic. Oxidase positive. Alkaline phosphatase, esterase, esterase lipase, lipase, leucine arylamidase, α-glucosidase, pyrazinamidase, pyrrolidonyl arylamidase, and gelatin hydrolysis detected. No activity is observed for nitrate reduction, valine and cystine arylamidases, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α- and β-galactosidases, β-glucuronidase, β-glucosidase, urease, *N*-acetyl-β-glucosaminidase, α-mannosidase, or α-fucosidase. The strain oxidizes the following carbon compounds as sole energy sources: maltose, lactulose, β-hydroxybutyric acid, α-ketovaleric acid, Tween 40, phenylethylamine, *N*-acetyl-D-galactosamine, malonic acid, L-threonine, L-glutamic acid, L-fucose, L-alanyl glycine, inosine and, less efficiently, raffinose, D-arabitol, L-asparagine, and citric acid, as determined with the Biolog GN system.

Cellular fatty acids are consistent with those described for the genus, with tuberculostearic acid detected. Mycolic acids (C_{30}–C_{36}) are present.

Source: the mucus of the coral *Fungia granulosa*, Gulf of Eilat, Red Sea.

DNA G+C content (mol%): 66.6 (HPLC).

Type strain: Coryn-1, DSM 45190, JCM 17108, LMG 24561.

Sequence accession no. (16S rRNA gene): FJ423600.

46. **Corynebacterium massiliense** Merhej, Falsen, Raoult and Roux 2009, 1958[VP]

mas.si.li.en′se. L. neut. adj. *massiliense* of or pertaining to *Massilia*, the old Roman name for Marseille from where the type strain was isolated.

Gram-stain-positive club-shaped rods, occurring as single cells, in pairs, or small clusters, 0.2–1.8 μm in length and 0.3–0.7 μm in diameter after 48 h growth in TSB medium. Colonies are circular, grayish, glistening, and 0.5–1 mm in diameter after growth on blood agar for 48 h. Capable of aerobic growth with only weak growth anaerobically and microaerophilically. Temperature range 30–44°C (optimum, 37°C). With the API Coryne system, acid is not produced from D-glucose, D-ribose, D-xylose, D-mannitol, maltose, D-lactose, sucrose, or glycogen. Nitrate is not reduced. Urea, gelatin, and esculin are not hydrolyzed. With API Coryne and API ZYM strips, positive for leucine arylamidase, weakly positive for pyrazinamidase, alkaline phosphatase, esterase and esterase lipase, but negative for pyrrolidonyl arylamidase, lipase, valine arylamidase, cystine arylamidase, trypsin, a-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase.

Cellular fatty acids are consistent with those described for the genus, and tuberculostearic acid may be detected. Testing for corynemycolates or other cell wall markers not done.

Source: human clinical materials.

DNA G+C content (mol%): not available.

Type strain: 5402485, CCUG 53857, CIP 109423, CSUR P19.

Sequence accession no. (16S rRNA gene): EF217056.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EF217057.

47. **Corynebacterium mastitidis** Fernández-Garayzábal, Collins, Hutson, Fernandez, Monasterio, Marco and Dominguez 1997, 1084[VP]

mas.ti′ti.dis. N.L. gen. n. *mastitidis* of an inflammation of the mammary gland.

Gram-stain-positive rods occurring singly, in palisades, or V-shaped forms. On blood agar, small (diameter less than 1 mm), rough, whitish, low convex colonies formed after 3 d of incubation at 37°C. Nonhemolytic. Esculin and gelatin not hydrolyzed, and nitrate not reduced. Hydrolysis of urea variable. Acid is not produced from glucose, ribose, xylose, mannitol, lactose, maltose, sucrose, and glycogen. Pyrazinamidase, alkaline phosphatase, acid phosphatase, esterase, esterase lipase, lipase, leucine arylamidase, valine arylamidase, and cystine arylamidase are produced. Pyrrolidonylarylamidase, β-glucuronidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, α-mannosidase, α-fucosidase, *N*-acetyl-*β*-glucosaminidase, trypsin, and chymotrypsin are not produced. The strains do not grow in the presence of 6.5% NaCl. The type strain has characteristics of the species described above except that it is urease and naphthol-AS-BI-phosphate positive.

The cell wall contains *meso*-DAP. Short-chain mycolic acids are present. The major long-chain fatty acids are $C_{16:0}$, $C_{18:0}$, and $C_{18:1}$ ω9*c*. Tuberculostearic acid is not produced.

Source: milk and udder of infected sheep, but strains genetically most like *Corynebacterium mastitidis* have been found to cause human ocular infections (Eguchi et al., 2008).

DNA G+C content (mol%): not available.

Type strain: S-8, CCUG 38654, CECT 4843, CIP 105509, DSM 44356, JCM 12269, LMG 19040, NBRC 16160.

Sequence accession no. (16S rRNA gene): Y09806.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492281. Sheep strains are susceptible to penicillin G, ampicillin, amoxycillin-clavulanic acid, gentamicin, cephalothin, and nalidixic acid. However, the strains described by Eguchi, which by 16S rRNA gene sequencing were closest to (98.2% identity) *Corynebacterium mastitidis* from human ocular infections, were generally susceptible to antimicrobics tested (Eguchi et al., 2008).

48. **Corynebacterium matruchotii** (Mendel 1919) Collins 1983, 438[VP] (Effective publication: Collins 1982a, 365.) (*Cladothrix matruchoti* Mendel 1919, 584; *Bacterionema matruchotii* Gilmour, Howell and Bibby 1961, 139)

ma.tru.cho'ti.i. N.L. gen. masc. n. *matruchotii* of Matruchot; named after Professor Matruchot, a French mycologist.

(This description also includes information from Collins and Cummins, 1986.)

Cells are pleomorphic, comprising nonseptate and septate filaments and bacilli. Characteristic morphology is a bacillus attached to a filament ("whip-handle"). Branching is frequent with aerobic and/or acidic conditions. Metachromatic granules formed. Colony appearance is variable; aerobically incubated colonies are 0.5–1.5 mm in diameter, circular, convex, rough with entire or filamentous margin or irregular "molar-toothed" rough colonies. May be 1–2 mm and adherent if grown anaerobically. *Corynebacterium matruchotii* colonies at 37°C on TBSA have also been described as being 1 mm in diameter, white, creamy or gray, with smooth matte surface and creamy texture; some strains have a crinkled surface and can be lifted as a single dry colony when touched by a loop (Rassoulian-Barrett et al., 2001). Facultatively anaerobic. Optimal temperature 37°C. Complex nutritional requirements. Positive for glucose, fructose, mannose, maltose, sucrose, salicin, and dextrin. Negative for arabinose, xylose, rhamnose, galactose, lactose, and trehalose. Raffinose and starch fermentation variable. Nitrate is reduced and hippurate hydrolyzed. Gelatin is hydrolyzed, and casein is not digested; methyl red, and phosphatase are negative. Esculin and urea hydrolysis described originally as being positive or occasionally positive. Rassoulian-Barrett et al., based on study of genetically characterized strains, found that *Corynebacterium matruchotii* isolates were conventional tube esculin test negative but could be esculin positive when using the API CORYNE strip; strains were urease and mannitol negative by both methods (Rassoulian-Barrett et al., 2001). The production of pyrrolidonyl arylamidase was the only trait that consistently distinguished *Corynebacterium matruchotii* strains from *Corynebacterium durum* strains which are otherwise very similar to each other biochemically (Rassoulian-Barrett et al., 2001).

meso-DAP is detected, and arabinose and galactose are cell-wall sugars. Cellular fatty acids were consistent with those described for the genus, but tuberculostearic acid is not detected. Species contains corynemycolates. Principal menaquinones are MK-9(H_2) and MK-8(H_2). Polar lipids include diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol dimannosides, and unidentified glycolipids. Propionic acid is produced as a metabolic product (Riegel et al., 1997a).

Source: the oral cavity, particularly from calculus and plaque deposits; is otherwise an occasional pathogen of humans or primates.

DNA G+C content (mol%): 55–58 (T_m).

Type strain: ATCC 14266, CCUG 27545, CCUG 46620, CIP 81.82, DSM 20635, JCM 9386, NBRC 15360, NCTC 10254.

Sequence accession no. (16S rRNA gene): X82065, X84443.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492238.

49. **Corynebacterium minutissimum** (*ex* Sarkany, Taplin and Blank 1962) Collins and Jones 1983a, 870[VP] emend. Yassin, Steiner and Ludwig 2002a, 1004

mi.nu.tis'si.mum. L. sup. neut. adj. *minutissimum* very small.

Colonies on blood agar are circular, about 1 mm in diameter after 24 h, circular, slightly convex, shiny, moist, and not pigmented. When grown in the presence of rich media (e.g. 20% fetal calf serum), colonies may demonstrate a coral-red to orange fluorescence when illuminated by a Wood's lamp (365 nm). A coralloid precipitin in agar is formed after growth on BHI agar supplemented with 1% Tween 80 whether in air or in CO_2. No hemolysis on blood agar. Cells described as short, straight, or slightly curved rods (1–2 × 0.3–0.6 µm) arranged at right angles to give V-formations. Metachromatic granules may be observed. Facultatively anaerobic. Optimal temperature 37°C. Positive for glucose, fructose, maltose, mannose, hippurate, alkaline phosphatase, pyrazinamidase, and leucine arylamidase. Negative for xylose, lactose, raffinose, trehalose, starch, adonitol, amygdalin, arabinose, cellobiose, glycerol, glycogen, inulin, mannitol, melezitose, rhamnose, ribose, salicin, and sorbitol. Hippurate, sucrose, and mannose described

as positive or variable but later as negative, positive, and negative, respectively. Acetoin positive, but indole negative; nitrate is not reduced, and urease is not produced. Tyrosine hydrolyzed (Funke and Bernard, 2007), but esculin and gelatin are not. Casein is not digested and methyl red is negative. Acid phosphatase, arginine dihydrolase, esterase, ester lipase, lipase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, naphthol-AS-BL-phosphoydrolase, pyrrolidonyl arylamidase, valine arylamidase, cystine arylamidase, trypsin, and chymotrypsin were negative.

Cells contain *meso*-DAP with arabinose and galactose as cell-wall sugars. Menaquinones MK-8(H_2) and MK-9(H_2) are detected. Diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannoside, and unidentified glycolipids are found. Corynemycolates are present (De Briel et al., 1992). Cellular fatty acids are consistent with those of the genus, and tuberculostearic acid is detected (Bernard et al., 1991). Lactic, but not propionic, acid is produced as metabolic product.

Source: a rare opportunistic human pathogen.

DNA G+C content (mol%): 56–58 (HPLC).

Type strain: ATCC 23348, CCUG 541, CIP 100652, DSM 20651, JCM 9387, NBRC 15361, NCTC 10288.

Sequence accession no. (16S rRNA gene): X82064, X84678, X84679.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492235. Accession number for NCTC 10288 X84678 was described by the depositor as *Corynebacterium minutissimum* clone 1 and NCTC 10288 X84679 as clone 2, respectively. By 16S rRNA gene sequencing, *Corynebacterium minutissimum* is closely related to (>98.9–99% identity) *Corynebacterium aurimucosum* and *Corynebacterium singulare* (Riegel et al., 1997b), but differs from these (~93.8–94.6% identity, respectively) when partial or complete sequences of the *rpoB* gene are compared (Khamis et al., 2004). *Corynebacterium minutissimum* had long been attributed as a cause of erythrasma, a skin infection, but this inference has been challenged, as most publications citing this association did so in the absence of laboratory-based evidence (Coyle and Lipsky, 1990). It has been thought that some published *Corynebacterium minutissimum* reports in the past may actually represent misidentified *Corynebacterium amycolatum* strains (Zinkernagel et al., 1996).

50. **Corynebacterium mucifaciens** Funke, Lawson and Collins 1997d, 956[VP]

mu.ci.fa′ci.ens. L. n. *mucus* slime; L. part. adj. *faciens* producing; N.L. part. adj. *mucifaciens* slime producing.

Colonies on blood agar are highly unusual with respect to members of this genus, as they are circular, convex, glistening, yellowish, uniquely mucoid, and about 1–1.5 mm in diameter after 24 h incubation at 37°C in 5% CO_2. Facultatively anaerobic and nonhemolytic. Acid produced from glycerol, glucose, fructose, and mannose but not from erythritol, arabinose, xylose, adonitol, *p*-methyl-xyloside, galactose, L-sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, maltose, lactose, melibiose, trehalose, melezitose, D-raffinose, glycogen, *p*-gentiobiose, D-turanose, D-lyxose, D-tagatose, fucose, arabitol, gluconate, and 2-ketogluconate. Acid production from ribose and sucrose variable. Nitrate is not reduced. Urea and esculin are not hydrolyzed. Not lipophilic. CAMP reaction negative. Pyrazinamidase, alkaline phosphatase, esterase, esterase-lipase, cystine arylamidase, and acid phosphatase are positive, but pyrrolidonyl arylamidase and phosphoamidase are variable. Lipase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are not detected.

Cell wall contains *meso*-diaminopimelic acid. Mycolic acids are present. Propionic acid is not produced as a metabolic product (Bernard et al., 2002).

Source: human disease from various clinical materials.

DNA G+C content (mol%): 63–65 (HPLC).

Type strain: ATCC 700355, CCUG 36878, CIP 105129, DMMZ 2278, DSM 44265, JCM 10384.

Sequence accession no. (16S rRNA gene): Y11200.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492261. By 16S rRNA gene sequencing, *Corynebacterium mucifaciens* is closely related to (98% identity with) *Corynebacterium coyleae* and *Corynebacterium afermentans*, but differs from them (~94% identity with) when *rpoB* gene sequences are compared (Khamis et al., 2004).

51. **Corynebacterium mustelae** Funke, Frodl and Bernard 2010b, 873[VP]

mus.te′la.e. L. n. *mustela* a weasel, also a scientific zoological name; L. gen. *mustelae* of a weasel, of *Mustela*, indicating that the type strain was isolated from a ferret (*Mustela putorius furo*).

Gram-stain-positive club shaped rods. Unusual greenish-beige adherent colonies with irregular edges, ~1.0– 2 mm in diameter observed after 48 h. Has odor, described as "humid-cellar like". Nonlipophilic. Facultatively anaerobic. Acid is produced from ribose, glucose, fructose, mannose, *N*-acetylglucosamine, arbutin, maltose, sucrose, trehalose, gentiobiose, tagatose, L-fucose, and 5-ketogluconate, but not from glycerol, erythritol, L-arabinose, xylose, adonitol, methyl-β-xyloside, galactose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, amygdalin, salicin, cellobiose, lactose, melibiose, inulin, melezitose, raffinose, starch, glycogen, xylitol, turanose, lyxose, D-fucose, arabitol, gluconate, or 2-ketogluconate. The following enzymes are detected: pyrazinamidase, α-glucosidase, esculinase, esterase, esterase lipase, leucine and cystine arylamidases, and phosphoamidase but nitrate reductase, pyrrolidonyl arylamidase, urease, alkaline and acid phosphatases, lipase, valine arylamidase, trypsin, chymotrypsin, α- and β- galactosidases, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not. CAMP reaction negative.

The cell wall contains *meso*-DAP and mycolic acids. Cellular fatty acids are consistent with those of the genus, but tuberculostearic acid was not detected. The type strain was susceptible to all antibiotic classes tested.

Source: lung tissue at necropsy of a ferret with lethal sepsis.

DNA G+C content (mol%): not available.

Type strain: 3105, CCUG 57279, DSM 45274.

Sequence accession no. (16S rRNA gene): FJ374773.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) FJ467330.

52. **Corynebacterium mycetoides** (*ex* Castellani 1942) Collins 1983, 438[VP] (Effective publication: Collins 1982b, 399.) (*Corynebacterium mycetoides* (Castellani) Ortali and Capocaccia 1956, 490)

my.ce.to′i.des. Gr. n. *mukês -êtos* fungus; L. suff. *-oides* (from Gr. suff. *-eides* from Gr. n. *eidos* that which is seen, form, shape, figure) ressembling, similar; N.L. adj. *mycetoides* similar to fungi, referring to ulcers caused by fungi.

Surface colonies on blood or nutrient agar are ~1 mm in diameter after 2–3 d, circular, convex, entire margin, shiny, and yellow pigmented. Straight to slightly curved Gram-stain-positive rods 1–3 × 0.3–0.5 μm; V-forms and coccoidal forms may be observed. May stain unevenly, and metachromatic granules may be present.

Optimal growth temperature 37°C. Facultatively anaerobic. Glucose is fermented; fructose and trehalose are variable, but maltose, mannose, sucrose, arabinose, lactose, dextrin, cellobiose, galactose, raffinose, ribose, sorbose, xylose, melibiose, glycogen, adonitol, arbutin, inositol, and erythritol are not fermented. Gelatin, cellulose, and esculin not hydrolyzed. Indole, methyl red, and Voges–Proskauer negative. Nitrates not reduced, and urease not produced. Phosphatase positive.

Cell wall contains *meso*-DAP, with alanine and glutamic acid also being present. Arabinose and galactose are the cell-wall sugars. Corynemycolates (30–36 carbon atoms) present. Significant quantities of unusual, α-alkylbranches with odd numbers of carbon atoms such as $C_{15}H_{31}$ are detected. Metabolic products are not extant. Cellular fatty acids typical of the genus are detected including the presence of tuberculostearic acid (Bernard et al., 1991). Menaquinones MK-8(H_2) with small amounts of MK-9(H_2) found. Diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside, as well as unknown glycolipids and some unknown glycolipids and phospholipids are found.

Source: a type of ulcer (tropicaloid ulcer) on the legs of soldiers in the desert regions of North Africa in 1942; not reported in recent literature.

DNA G+C content (mol%): 59 (T_m).

Type strain: ATCC 43995, CCUG 27538, CIP 55.51, DSM 20632, JCM 9388, NBRC 15289, NCTC 9864.

Sequence accession no. (16S rRNA gene): X82066, X84241.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492262.

53. **Corynebacterium phocae** Pascual, Foster, Alvarez and Collins 1998, 603[VP]

pho′ca′e. L. n. *phoca* a seal and also a scientific genus name (*Phoca*); L. gen. n. *phocae* of a seal, of *Phoca*, named because the organism was isolated from the common seal, *Phoca vitulina.*

Cells are Gram-stain-positive short diphtheroids. Colonies are circular, convex, and slightly glistening. The colony diameter is ~1 mm after 24 h incubation on sheep blood agar at 37°C. Facultatively anaerobic. Acid is produced from D-glucose, D-mannose, and maltose, but not from adonitol, D-arabitol, L-arabitol, D-arabinose, L-arabinose, amygdalin, arbutin, cellobiose, dulcitol, erythritol, D-fucose, L-fucose, D-fructose, galactose, β-gentiobiose, gluconate, glycerol, glycogen, inositol, inulin, 2-ketogluconate, D-lyxose, mannitol, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, β-methylxyloside, D-raffinose, rhamnose, salicin, sorbitol, L-sorbose, starch, D-tagatose, trehalose, D-turanose, xylitol, and xylose. Acid production from galactose, *N*-acetylglucosamine, lactose, sucrose, and D-raffinose is variable. Nitrate not reduced to nitrite, and urea hydrolysis variable. Esculin and gelatin are not hydrolyzed. Pyrazinamidase, alkaline phosphatase, esterase-lipase, acid phosphatase, and α-glucosidase are detected, but valine arylamidase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, esterase, lipase, cystine arylamidase, trypsin, and α-fucosidase activities are not detected. Leucine arylamidase activity variable.

The cell wall contains *meso*-DAP, and mycolic acids (C_{30}–C_{34}) are present. Cellular fatty acids are consistent with those found for the genus, but tuberculostearic acid is not produced.

Source: the common seal (*Phoca vitulina*).

DNA G+C content (mol%): 58 (method unknown).

Type strain: M408/89/1, CCUG 38205, CIP 105741, DSM 44612, JCM 12105.

Sequence accession no. (16S rRNA gene): Y10076.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492277. Strain M408/89/1 has the characteristics described for the species except that it produces urease and has a negative leucine arylamidase reaction. M408/89/1 produces acid from galactose but not from D-fructose, *N*-acetylglucosamine, lactose, sucrose, and D-raffinose.

54. **Corynebacterium pilbarense** Aravena-Roman, Spröer, Sträubler, Inglis and Yassin 2010, 1486[VP]

pil.ba.ren′se. N.L. neut. adj. *pilbarense* pertaining to Pilbara, Western Australia, the region from which the strain was isolated.

Gram-stain-positive pleomorphic to short rods. Colonies are creamy, circular, and approximately 0.5–2.0 mm in diameter on Columbia blood agar after 24 h incubation at 37°C. Nonhemolytic. Facultatively anaerobic. Nonlipophilic. Esculin, gelatin, and hippurate are not hydrolyzed. Urease and nitrate reduction are negative. Acid is produced from D-glucose, D-ribose, and sucrose. Acid is not produced from L-arabinose, glycogen, inulin, lactose, maltose, mannitol, D-raffinose, sorbitol, trehalose, or D-xylose. Activity for alkaline and acid phosphatases, leucine arylamidase, pyrazinamidase, pyrrolidonyl arylamidase, and naphthol-AS-BI-phosphohydrolase are detected. No activity is detected for arginine dihydrolase, esterase, ester lipase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase,

α-fucosidase, chymotrypsin, trypsin, valine arylamidase, and cystine arylamidase. Acetoin production was negative.

Mycolic acids are present. Long-chain fatty acids are typical for those of the genus, but tuberculostearic acid is absent.

Source: an anaerobic Bactec vial inoculated with ankle aspirate from a man who was thought to be suffering from gout.

DNA G+C content (mol%): not available.

Type strain: IMMIB WACC 658, CCUG 57942, DSM 45350.

Sequence accession no. (16S rRNA gene): FN295567.

55. **Corynebacterium pilosum** Yanagawa and Honda 1978, 209[AL]

pi.lo′sum. L. neut. adj. *pilosum* having much hair; intended to mean having many fimbriae (pili).

(This description also contains information from Collins and Cummins, 1986.)

Gram-stain-positive rods, 0.5 × 1.3 µm, arranged as singly, pairs often at angles, or in irregular masses. Metachromatic granules present. Numerous fimbriae or pili observed using electron microscopy. Colonies on nutrient agar and serum agar are cream to pale yellow, entire, circular, opaque, and about 1 mm in diameter after 24 h incubation at 37°C. No hemolysis on sheep, guinea pig, or rabbit blood agar. Facultatively anaerobic. Pellicle and granular sediment formed in broth. No growth at 5°C or 41.5°C, but cells remain viable for 30 min at 56°C. Complex amino acid requirements. Positive for glucose, fructose, mannose, maltose, trehalose, dextrin, and starch; negative for arabinose, xylose, rhamnose, galactose, lactose, sucrose, raffinose, and salicin. Nitrate is reduced, urease is produced, hippurate is hydrolyzed, and pyrazinamidase is detected. Esculin, tyrosine, and gelatin are not hydrolyzed; casein is not digested; methyl red and phosphatase are negative.

meso-DAP and the sugars arabinose and galactose are present. Short-chain mycolates are present (De Briel et al., 1992). Menaquinone MK-8(H_2) detected. Cellular fatty acids are consistent with those found for the genus, and tuberculostearic acid is detected (Bernard et al., 1991).

Source: the urine and vagina of healthy cows, but occasionally causes cystitis and pyelonephritis.

DNA G+C content (mol%): 57.9–60.9 (T_m).

Type strain: 46 Hara, ATCC 29592, CCUG 27193, CIP 103422, DSM 20521, JCM 3714, NBRC 15285, NCTC 11862.

Sequence accession no. (16S rRNA gene): X81908, X84246.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492258.

56. **Corynebacterium propinquum** Riegel, de Briel, Prévost, Jehl and Monteil 1994a, 370[VP] (Effective publication: Riegel, de Briel, Prévost, Jehl and Monteil 1993a, 232.)

pro.pin′qu.um. L. neut. adj. *propinquum* near, close.

Gram-stain-positive with occasional metachromatic granules and arranged in palisades or V-shaped forms. Colonies (1–2 mm in diameter) on 5% sheep blood agar, nonhemolytic, gray-white with a matted surface. Facultatively anaerobic. Characteristically "ANF", i.e. an absolute nonfermenter, but reduces nitrate to nitrite. Acid is not produced from D-glucose, glycogen, lactose, sucrose, ribose, D-xylose, D-mannose, D-galactose, trehalose, and D-mannitol or on triple-sugar iron agar. Tyrosine degraded but gelatin, starch, and urea are not. Esculin not hydrolyzed. The methyl red test is negative; acetoin not produced. Growth is visible in 6.5% NaCl. Hydrolysis of hippurate is variable. Production of pyrazinamidase, pyrrolidonyl arylamidase, alkaline phosphatase is variable, but β-glucuronidase, β-galactosidase, α-glucosidase, *N*-acetyl-glucosaminidase are not produced. Cells utilize acetate, lactate, glyconate, and malate. Utilization of adipate and phenyl acetate is variable. Propionate, glucose, arabinose, mannose, mannitol, *N*-acetylglucosamine, maltose, caprate, and citrate are not utilized.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose. The predominant types of mycolic acids are isomers with 30–36 carbons. Cellular fatty acids are consistent with those of the genus.

Source: human sources, mainly from the respiratory tract, but also from other sites.

DNA G+C content (mol%): 57–59 (HPLC).

Type strain: B 77159, ATCC 51488, CCUG 33048, CIP 103792, DSM 44285, JCM 12106.

Sequence accession no. (16S rRNA gene): X81917, X84438.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492279.

Corynebacterium propinquum was formerly called *Corynebacterium* group ANF-3. Species has <2% variance by 16S rRNA gene sequencing analysis from *Corynebacterium pseudodiphtheriticum*, but may be distinguished by *rpoB* analysis (Khamis et al., 2004).

57. **Corynebacterium pseudodiphtheriticum** Lehmann and Neumann 1896, 361[AL]

Historically, this species has been described by a number of synonyms, including "*Bacillus pseudodiphtheriticus*" (Lehmann and Neumann 1896) Kruse 1886, "*Bacterium pseudodiphtheriticum*" (Lehmann and Neumann 1896) Migula 1900, "*Mycobacterium pseudodiphthericum*" (*sic*) (Lehmann and Neumann 1896) Chester 1901, "*Corynebacterium pseudodiphthericum*" (*sic*) (Lehmann and Neumann 1896) Bergey et al. 1925 and had also been referred to as "*Corynebacterium hofmannii*" Holland 1920, a name which was never validly published.

pseu.do.diph.the.ri′ti.cum. Gr. adj. *pseudes* false; N.L. fem. n. *diphtheria* diphtheria; N.L. adj. *diphtheriticus -a -um* diphtheric; N.L. neut. adj. *pseudodiphtheriticum* relating to false diphtheria.

(This description is largely based on that of Collins and Cummins, 1986.)

Short (0.5–2.0 × 0.3–0.5 µm), regular Gram-stain-positive rods which stain evenly except for a transverse medial unstained septum; club forms seen. Metachromatic granules absent or minimally observed. Organisms said to lie in rows with long axes parallel. Grows well on all media. When grown on blood agar, colonies are white to cream colored, regular and smooth, butyrous consistency, and are nonhemolytic. Facultatively anaerobic. Characteristically does not attack commonly used carbohydrates, although it

can utilize a wide variety of amides, esters, amino acids, and other organic compounds. Organisms reduce nitrate and hydrolyze urea. Hippurate and pyrazinamidase positive but negative for phosphatase. Optimal temperature 37°C.

Cell-wall sugars are arabinose, galactose, and glucose, and contains *meso*-DAP. Corynemycolates are present. Cellular fatty acids are consistent with those found for the genus (Bernard et al., 1991). Propionic acid is not produced as metabolic product (Bernard et al., 2002).

Source: nasal mucosa and various human clinical materials.

DNA G+C content (mol%): 54.9–56.8 (T_m).

Type strain: ATCC 10700, CCUG 27539, CIP 103420, DSM 44287, JCM 11665, NBRC 15362, NCTC 11136.

Sequence accession no. (16S rRNA gene): AJ439343, X81918, X84258.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492232. Species has <2% variance by 16S rRNA gene sequencing analysis from *Corynebacterium propinquum*, but may be distinguished by *rpoB* analysis (Khamis et al., 2004). Although occasionally present in flora of the upper respiratory tract in healthy individuals, this agent has been associated with exudative pharyngitis mimicking diphtheria, occasionally provoking public health response (Izurieta et al., 1997); recognized as cause of pneumonia, endocarditis, lymphadenitis, keratitis, conjunctivitis, and septic arthritis. Diseases caused by this agent and clinical sites of recovery have been reviewed (Camello et al., 2009). *Corynebacterium pseudodiphtheriticum* strains can be multidrug resistant, which has been linked to the presence of the *ermX* gene (Olender and Niemcewicz, 2010).

58. **Corynebacterium pseudotuberculosis** (Buchanan 1911) Eberson 1918, 294[AL]

Synonyms: "*Bacillus pseudotuberculosis-ovis*" Lehmann and Neumann 1896, "*Bacillus pseudotuberculosis*" Buchanan 1911, "*Corynebacterium ovis*" Bergey et al. 1923, "*Corynebacterium pseudotuberculosis-ovis*" (Lehmann and Neumann 1896) Hauduroy et al. 1937, "*Corynebacterium preisz-nocardi*" Hauduroy et al. 1937, "*Mycobacterium tuberculosis-ovis*" Krasil'nikov 1941.

pseu.do.tu.ber.cu.lo′sis. Gr. adj. *pseudes* false; N.L. fem. n. *tuberculosis* tuberculosis; N.L. gen. n. *pseudotuberculosis* of false tuberculosis.

(This description is largely based on that of Collins and Cummins, 1986.)

In stained smears, described as being similar to *Corynebacterium diphtheriae*, especially the gravis type, with small irregular rods, 0.5–0.6 × 1.0–3.0 µm, with club forms and metachromatic granules. Fimbriae (pili) may be observed. Colonies on blood agar are yellowish-white, opaque, convex with a matt surface, about 1 mm after 24 h incubation at 37°C. Hemolysis may be observed on horse blood agar (Peel et al., 1997). Like *Corynebacterium diphtheriae* and *Corynebacterium ulcerans*, *Corynebacterium pseudotuberculosis* produces cystinase, as demonstrated by production of brown colonies and haloes when grown on modified Tinsdale medium. Facultatively anaerobic. Positive for glucose, fructose, galactose, mannose, and maltose. Urease production and methyl red are positive. Variable for arabinose, sucrose, dextrin, and trehalose; variable for gelatin, nitrate reduction, and starch hydrolysis. Negative for xylose, rhamnose, lactose, raffinose, and salicin. Negative for esculin and hippurate hydrolysis. Neither pyrazinamidase nor phosphatase is detected. Tyrosine is not hydrolyzed, and casein is not digested. Biochemically, this species is most similar to urease-producing *Corynebacterium ulcerans* but differs by occasionally reducing nitrate and being negative or rarely reactive with starch, glycogen, or trehalose (Dorella et al., 2006; Hollis and Weaver, 1981; Peel et al., 1997).

Cell walls contain arabinose, galactose, glucose, and mannose and *meso*-DAP. Menaquinone MK-8(H_2) is present. Polar lipids detected include diphosphatidylglycerol, phosphatidylinositol, and monoacylated phosphatidylinositol dimannoside. Corynemycolates are present. Cellular fatty acids are those described for the genus except, as for cysteinase-producing species *Corynebacterium diphtheriae*, *Corynebacterium pseudotuberculosis*, and *Corynebacterium ulcerans*, has significant quantities of a $C_{16:1}$ isomer. Tuberculostearic acid is not detected (Bernard et al., 1991). Propionic acid is detected as a fermentation product (Bernard et al., 2002).

Source: infections in sheep, goats, horses, and other warm-blooded animals; occasionally linked to disease in humans.

DNA G+C content (mol%): 51.8–52.5 (T_m).

Type strain: ATCC 19410, CCUG 2806, CIP 102968, DSM 20689, JCM 9389, NBRC 15363, NCTC 3450.

Sequence accession no. (16S rRNA gene): X81916, X84255.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492239. *Corynebacterium pseudotuberculosis* and *Corynebacterium ulcerans* are the only *Corynebacterium* species to produce phospholipase D (PLD), with expression of the *pld* gene product being detected by inhibition of the CAMP reaction (Barksdale et al., 1981). PLD is believed to be a major virulence determinant for spread of caseous lymphadenitis, a disease primarily of sheep and goats. PLD spreads the bacterium from the site of infection to the lymph nodes followed by caseation by means of a complex regulatory process (McKean et al., 2007). Disease in humans is usually occupationally linked to those who handle infected animals (McKean et al., 2007; Peel et al., 1997). Detection of the *pld* gene has been used clinically to diagnose diseased animals (Pacheco et al., 2007). *Corynebacterium pseudotuberculosis* isolates may produce diphtheria toxin with the potential to cause diphtherial-like disease, which clinically should be tested for (as described elsewhere in this chapter). Nontoxigenic strains otherwise have typical features. By 16S rRNA gene sequencing, *Corynebacterium pseudotuberculosis* is most closely related to (>99% identity with) *Corynebacterium ulcerans* and to (>97% identity with) *Corynebacterium diphtheriae*, but *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis* are only distantly related (93% level) when *rpoB* gene sequences are compared (Khamis et al., 2004).

59. **Corynebacterium pyruviciproducens** Tong, Liu, Summanen, Xu and Finegold 2010, 1139[VP]

py.ru.vi.ci.pro.du′cens. N.L. n. *acidum pyruvicum* pyruvic acid; L. part. adj. *producens* producing; N.L. part. adj. *pyruviciproducens* pyruvic acid-producing.

Gram-stain-positive coryneform rods. Lipophilic. Can grow aerobically or facultatively anaerobically at 37°C and

42°C. Optimum growth at 37°C under aerobic conditions. Colonies are small, i.e., 0.3–0.5 mm in diameter, circular, entire, convex, and translucent after 2 d of incubation on blood agar. Urease negative. Cannot reduce nitrates. CAMP negative. Acid is produced from D-ribose, D-xylose, D-glucose, maltose, and sucrose, but not from fructose, D-mannitol, lactose, or glycogen. Cells produce esterase, esterase lipase, leucine arylamidase, pyrazinamidase, a small amount of naphthol-AS-BI-phosphohydrolase, and pyrrolidonyl arylamidase, but not acid phosphatase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, lipase, valine arylamidase, cystine arylamidase, α-chymotrypsin, α-galactosidase, α-fucosidase, alkaline phosphatase, α-mannosidase, or β-glucosidase. Trypsin and gelatin are not hydrolyzed. β-Lactamase negative. Susceptible to the vibriostatic agent O/129 and highly sensitive to ampicillin, ceftriaxone, clindamycin, and erythromycin.

Cellular fatty acids are consistent for those of the genus, but no tuberculostearic acid is detected. Short-chain mycolic acids (C_{22}–C_{36}) are present. Metabolic products include acetic and pyruvic acids but not propionic.

Source: a human groin abscess.

DNA G+C content (mol%): 62 (HPLC).

Type strain: 06–17730, ATCC BAA-1742, CCUG 57046, WAL 19168.

Sequence accession no. (16S rRNA gene): FJ185225.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) FJ899747.

60. **Corynebacterium renale** (Migula 1900) Ernst 1906, 89[AL] (*Bacterium renale* Migula 1900, 504)

re.na′le. L. neut. adj. *renale* pertaining to the kidneys.

(This description is largely based on that of Collins and Cummins, 1986.)

Large, irregularly staining bacillus, 0.7 × 3.0 µm, often with pointed ends; fimbriae (pili) may be present after examination by electron microscopy. Colonies on blood agar are yellow pigmented after 24 h incubation at 37°C. Grows in broth at pH 5.4. Facultatively anaerobic. Positive for glucose, fructose, mannose, and dextrin. Variable for maltose and trehalose. Negative for arabinose, xylose, rhamnose, galactose, lactose, sucrose, raffinose, starch, and salicin. Urease production and methyl red are positive. Hippurate hydrolysis positive. Pyrazinamidase positive, but phosphatase negative. Esculin, tyrosine, and gelatin are not hydrolyzed. Casein is digested. Nitrate is not reduced.

Corynemycolates (30–36 carbons) and menaquinone MK-8(H_2) are present. Cellular fatty acids consistent with those for the genus are found, but tuberculostearic acid is not detected. Propionic acid is not detected as fermentation product (Bernard et al., 2002).

Source: cystitis and pyelitis in cattle and occasionally in other animals. Disease in humans described historically, but no genetic confirmation.

DNA G+C content (mol%): 53–58 (T_m).

Type strain: ATCC 19412, CCUG 27542, CIP 103421, DSM 20688, HAMBI 2321, JCM 9391, NBRC 15290, NCTC 7448.

Sequence accession no. (16S rRNA gene): X81909, X84249.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) Y492240.

61. **Corynebacterium resistens** Otsuka, Kawamura, Koyama, Iihara, Ohkusu and Ezaki 2005b, 2235[VP] (Effective publication: Otsuka, Kawamura, Koyama, Iihara, Ohkusu and Ezaki 2005a, 3716.)

re.sis.tens. L. part. adj. *resistens* enduring, resistant (multidrug-resistant).

Cells are Gram-stain-positive, typically club-shaped rods, 1–3 µm in length, and arranged as single cells, in pairs, or in small clusters. Growth on TSA with 5% sheep blood produces nonpigmented, grayish-white, glistening, pearly colonies up to 1.0 mm in diameter. Colonies are nonhemolytic and very slow-growing under anaerobic conditions. Tween 80 enhances growth, resulting in colonies 2–4 mm in diameter, i.e. strains are lipophilic. CAMP negative. Nitrate not reduced. Ferments D-tagatose, 5-ketogluconate, ribose, and D-glucose with trehalose and L-sorbose being variable. Negative for glycerol, erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, β-methylxyloside, galactose, D-fructose, D-mannose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, β-gentiobiose, D-turanose, D-lyxose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, and 2-ketogluconate. Alkaline phosphatase, esterase, esterase lipase, leucine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase strongly positive, but lipase, cysteine, and arylamidase are weakly positive. Reactions for pyrazinamidase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are negative.

Cellular fatty acids are consistent for those described for the genus; other chemotaxonomic information is not extant.

Source: human disease from bacteremias of leukemic patients, bronchial aspirates of patients with lymphoma or subarachnoid hemorrhaging, and a patient with cellulitis.

DNA G+C content (mol%): 54.643 (standard deviation, 0.03%) (HPLC).

Type strain: CCUG 50093, GTC 2026, JCM 12819, SICGH 158.

Sequence accession no. (16S rRNA gene): AB128981.

Further comments: Corynebacterium resistens is resistant to multiple drug classes, but all strains are susceptible to vancomycin.

62. **Corynebacterium riegelii** Funke, Lawson and Collins 1998b, 627[VP] (Effective publication: Funke, Lawson and Collins 1998a, 626.)

ri.e.gel′i.i. N.L. gen. masc. n. *riegelii* of Riegel, to honor contemporary French microbiologist Philippe Riegel for his contributions to the taxonomy of the genus *Corynebacterium* as well as to the clinical microbiology of coryneform bacteria.

Gram-stain-positive typically club-shaped rods which appear as single cells, in pairs, or in small clusters. Colonies are whitish with a creamy or a slightly sticky consistency, circular with entire edges, convex, glistening, and up to 1.5 mm

in diameter after 48 h of incubation. Weak growth anaerobically. Biochemically unusual, as acid is produced from maltose, ribose, trehalose, D-tagatose, and 5-ketogluconate, but not produced from glucose, sucrose, mannitol, xylose, glycerol, erythritol, arabinose, adonitol, β-methylxyloside, galactose, D-fructose, D-mannose, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, lactose, melibiose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, β-gentiobiose, D-turanose, D-lyxose, fucose, arabitol, gluconate, or 2-ketogluconate. Nitrate is not reduced. Urea hydrolysis strongly positive, but esculin not hydrolyzed. CAMP reaction negative. Esterase, esterase lipase, leucine arylamidase, and cystine arylamidase detected, but pyrazinamidase and alkaline and acid phosphatases are variable. Pyrrolidonylarylamidase, lipase, valine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not detected. The type strain has features as described above except that the activity of alkaline phosphatase but not that of pyrazinamidase or acid phosphatase is detected.

The cell wall contains *meso*-DAP. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not detected. Propionic acid is not produced as a metabolic product (Bernard et al., 2002).

Source: human clinical specimens.

DNA G+C content (mol%): not available.

Type strain: ATCC 700782, CCUG 38180, CIP 105310, DMMZ 2415, DSM 44326, JCM 10389.

Sequence accession no. (16S rRNA gene): Y14651.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492278.

63. **Corynebacterium simulans** Wattiau, Janssens and Wauters 2000, 351[VP]

si′mu.lans. L. part. adj. *simulans* simulating, because it resembles *Corynebacterium striatum.*

Cells are Gram-stain-positive showing a diphtheroid arrangement. Colonies are grayish-white, glistening, and 1–2 mm in diameter on blood agar after 48 h incubation at 37°C. Facultatively anaerobic. Fermentative. Growth does not occur or is very weak at 20°C within 3 d. Acid is produced from glucose, sucrose, fructose, and mannose. Acid production from *N*-acetylglucosamine, galactose, and ribose is variable. Acid is not produced from mannitol, maltose, D- and L-xylose, glycerol, erythritol, D- and L-arabinose, adonitol, methyl-β-D-xyloside, sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl-α,D-mannoside, methyl-α,D-glucoside, amygdalin, arbutin, esculin, salicin, cellobiose, lactose, melibiose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D- and L-fucose, D- and L-arabitol, gluconate, 2-ketogluconate, and 5-keto-gluconate. Urea, esculin, and gelatin not hydrolyzed. Nitrate and nitrite reduction positive, a feature unique among all *Corynebacterium* species with nitrite reduction occurring at concentrations of 0.001–0.01%.

Alkalinization of buffered formate is positive. No acid produced from ethylene glycol. Tween esterase and tyrosine clearing positive. Pyrazinamidase is variable. CAMP reaction negative. Alkaline phosphatase, esterase, esterase-lipase, leucine arylamidase, trypsin, and naphthol-AS-BI-phosphohydrolase positive but lipase, valine arylamidase, cystine arylamidase, chymotrypsin, acid phosphatase, α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase negative. The type strain of *Corynebacterium simulans* is as described here with ribose, *N*-acetylglucosamine, galactose, and pyrazinamidase being positive. Cell wall contains the sugars arabinose and galactose as well as *meso*-DAP. Cellular fatty acids are consistent with those described for the genus. Short-chain mycolic acids (C_{22}–C_{36}) are present. Propionic acid is not detected as a metabolic product (Bernard et al., 2002).

Source: human clinical materials including bile (Bernard et al., 2002; Wattiau et al., 2000).

DNA G+C content (mol%): not available.

Type strain: Co 553, ATCC BAA-15, CCUG 43305, CIP 106488, DSM 44415, JCM 12107, UCL 553.

Sequence accession no. (16S rRNA gene): AJ012837.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492264.

64. **Corynebacterium singulare** Riegel, Ruimy, Renaud, Freney, Prévost, Jehl, Christen and Monteil 1997b, 1095[VP]

sin.gu.la′re. L. neut. adj. *singulare* single, unique.

Gram-stain-positive irregular rods arranged in typical V-shaped forms or palisades. Facultatively anaerobic. Nonhemolytic colonies (1–2 mm diameter) grayish and smooth after 24 h at 37°C on sheep blood agar. Colonies circular and slightly convex with entire margins. Nitrate is not reduced to nitrite. Urea and tyrosine degraded, but gelatin and esculin are not hydrolyzed. Acid is produced from glucose, maltose, and sucrose but not from lactose, glycogen, ribose, trehalose, mannitol, and D-xylose. Alkaline phosphatase, pyrrolidonylarylamidase, and pyrazinamidase are produced but α-glucosidase, β-glucuronidase, β-galactosidase, and *N*-acetyl-β-glucosaminidase are not. Cells utilize D-glucose, D-fructose, D-trehalose, D-mannose, sucrose, maltose, glycerol, D-turanose, L-malate, phenylacetate, putrescine, DL-lactate, caprylate, L-histidine, succinate, fumarate, 3-hydroxybutyrate, L-aspartate, L-glutamate, D-alanine, L-serine, propionate, and L-tyrosine as sole carbon sources. D-Ribose, *N*-acetyl-D-glucosamine, and D-gluconate are not utilized.

Cell wall contains *meso*-DAP, the sugars arabinose and galactose, and short-chain mycolic acids (C_{26}–C_{36}). Cellular fatty acids are consistent with those described for the genus. Propionic acid is not produced by anaerobic metabolism of glucose.

Source: human semen.

DNA G+C content (mol%): 62 (capillary electrophoresis).

Type strain: CCUG 37330, CIP 105491, DSM 44357, IBS B52218, JCM 10385, NBRC 16162.

Sequence accession no. (16S rRNA gene): Y10999.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492280.

By 16S rRNA gene sequencing alone, this species can not be readily discerned from *Corynebacterium aurimucosum* and *Corynebacterium minutissimum*, but these can be resolved using *rpoB* gene sequencing (Khamis et al., 2004).

65. **Corynebacterium sphenisci** Goyache, Ballesteros, Vela, Collins, Briones, Hutson, Potti, García-Borboroglu, Domínguez and Fernández-Garayzábal 2003a, 1011[VP]

sphe.nis′ci. N.L. masc. gen. n. *sphenisci* of *Spheniscus*, a systematic genus of penguins, source of the type strain.

Gram-stain-positive rods. Colonies are whitish, low-convex, dry and rough, ~1–2 mm in diameter after 48 h incubation at 37°C on sheep blood agar. Facultatively anaerobic. Nonhemolytic, nonlipophilic, and CAMP negative. Nitrates are reduced. Acid is produced from glucose, maltose, galactose, fructose, mannose, and trehalose, but not from ribose, sucrose, glycogen, xylose, mannitol, lactose, erythritol, D-arabinose, L-arabinose, adonitol, galactose, L-sorbose, rhamnose, inositol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, amygdalin, dulcitol, arbutin, salicin, cellobiose, melibiose, inulin, melezitose, D-raffinose, xylitol, β-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, *N*-acetylglucosamine, 2-ketogluconate, 5-ketogluconate, or glycerol. Gelatin, urea, and esculin are not hydrolyzed. Pyrazinamidase, esterase, ester lipase, lipase, leucine arylamidase, valine arylamidase, cystine arylamidase, chymotrypsin, acid phosphatase, and naphthol-AS-BI-phosphohydrolase detected, but alkaline phosphatase, pyrrolidonyl arylamidase, α-glucosidase, β-glucosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-galactosidase, β-galactosidase, α-fucosidase, and trypsin are not.

Cell-wall murein is based on *meso*-DAP. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present. Corynomycolates detected in small amounts.

Source: the cloaca of an apparently healthy wild magellanic penguin (*Spheniscus magellanicus*).

DNA G+C content (mol%): not available.

Type strain: CCUG 46398, CECT 5990, JCM 12270.

Sequence accession no. (16S rRNA gene): AJ440964.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EU004067 for DSM 44792.

66. **Corynebacterium spheniscorum** Goyache, Vela, Collins, Ballesteros, Briones, Moreno, Yorio, Domínguez, Hutson and Fernández-Garayzábal 2003b, 45[VP]

sphe.nis.co′rum. N.L. masc. n. *spheniscus* a genus of penguin; N.L. masc. pl. gen. n. *spheniscorum* of penguins.

Gram-stain-positive rods. Colonies are whitish, circular, smooth, entire, and ~ 1–2 mm diameter on Columbia blood agar after 24 h incubation at 37°C. Nonhemolytic.

Facultatively anaerobic; grows slightly under anaerobic conditions. Nonlipophilic, and CAMP-positive using *Staphylococcus aureus* in the test assay. Esculin, gelatin, and urea are not hydrolyzed. Nitrate not reduced. Acid is produced from glucose, ribose, D-fructose, D-mannose, trehalose, *N*-acetyl-β-glucosamine, and maltose, but not from D-xylose, L-xylose, mannitol, lactose, rhamnose, galactose, adonitol, inositol, D- or L-arabinose, sucrose, melibiose, melezitose, or glycogen. Acidification of dulcitol is variable. Enzyme activity for ester lipase, esterase, pyrazinamidase, and leucine arylamidase (weak) detected but not for alkaline and acid phosphatases, pyrrolidonyl arylamidase, α-glucosidase, β-glucosidase, β-glucuronidase, α-galactosidase, β-galactosidase, α-mannosidase, α-fucosidase, chymotrypsin, trypsin, valine arylamidase, cystine arylamidase, and naphthol-AS-BI-phosphohydrolase.

Cell wall contains *meso*-DAP, and Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present. Mycolic acids are present (C_{32}–C_{36}).

Source: the cloacae of apparently healthy penguins (*Spheniscus magellanicus*).

DNA G+C content (mol%): not available.

Type strain: PG 39, CCUG 45512, CECT 5986, JCM 12271.

Sequence accession no. (16S rRNA gene): AJ429234.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492283.

67. **Corynebacterium sputi** Yassin and Siering 2008, 2878[VP]

spu′ti. L. gen. n. *sputi* of sputum.

Gram-stain-positive rods. Colonies are cream-yellow, circular, convex, dry, and ~ 0.2–2 mm in diameter on Columbia blood agar after 48 h incubation at 37°C. Nonhemolytic. Lipophilic, as Tween 80 encourages growth of the organism. Facultatively anaerobic. Urea hydrolyzed, but esculin, gelatin, and hippurate are not. Nitrate not reduced. Acid produced from D-glucose but not from L-arabinose, glycogen, inulin, D-lactose, maltose, D-mannitol, raffinose, D-ribose, D-sorbitol, starch, sucrose, trehalose, or D-xylose. Activity detected for α-glucosidase, lipase, lipase, leucine arylamidase, pyrazinamidase, and naphthol-AS-BI-phosphohydrolase but not for acid and alkaline phosphatases, arginine dihydrolase, chymotrypsin, cysteine arylamidase, esterase, α-fucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, pyrrolidonyl arylamidase, trypsin, or valine arylamidase. Acetoin production negative.

Corynemycolic acids are present. Cellular fatty acids are consistent with those described for the genus, and tuberculostearic acid is present.

Source: the sputum of a patient with pneumonia.

DNA G+C content (mol%): not available.

Type strain: IMMIB L-999, CCUG 55795, DSM 45148.

Sequence accession no. (16S rRNA gene): AM930556.

68. **Corynebacterium stationis** (ZoBell and Upham 1944) Bernard, Wiebe, Burdz, Reimer, Ng, Singh, Schindle and Pacheco 2010, 877[VP] ("*Achromobacter stationis*" Zobell and Upham 1944, 273; *Brevibacterium stationis* Breed 1953, 14)

sta.ti.o′nis. L. gen. n. *stationis* of a fixed position.

Gram-stain-positive short rods, 0.6–1.0 µm in diameter, occurring singly, in pairs, in "V" forms, and can be club shaped. Colonies on blood agar after 24 h are gray-white but become yellowish with age, ~1 mm in diameter, raised, with no hemolysis observed. Facultatively anaerobic, but grows better under aerobic conditions. Poor or no growth under strictly anaerobic conditions. Grows at 25, 35, and 42°C in air. Nonlipophilic. Acid is produced, albeit slowly, from glucose, fructose, and ribose. Mannose and fucose found in the API 50CH gallery also weakly reactive. Xylose, mannitol, lactose, sucrose, maltose, galactose, glycerol, glycogen, raffinose, salicin, and trehalose are not reactive. Triple-sugar iron remains neutral or alkaline/neutral. Grows

in the presence of 6–10% NaCl. Urease produced. Nitrate reduced to nitrite, but nitrite is not reduced to nitrogen using either conventional or API Coryne panel methods. Simmons' citrate is alkalinized. Tyrosine is hydrolyzed, but gelatin, esculin, casein, and starch are not. Not reactive in tests for lysine, arginine, or ornithine decarboxylases. CAMP and CAMP-inhibition reactions not observed. DNase and indole are not produced. Pyrazinamidase may be produced, but otherwise most enzymes of the API ZYM panel are not detected. Strains are generally susceptible to a wide variety of antimicrobials.

Cell wall contains *meso*-DAP and the sugars are arabinose and galactose. Corynemycolates are present. Menaquinones MK-8(H_2) and MK-9(H_2) detected. Cellular fatty acids are consistent with those described for the genus. Propionic acid is not detected as metabolic product.

Source: sea water. ATCC 6872, previously identified as *Corynebacterium ammoniagenes* but now assigned to *Corynebacterium stationis*, was isolated from human infant stools. Additional strains were recovered from human blood cultures (Bernard et al., 2010).

DNA G+C content (mol%): 53.9 (T_m).

Type strain: ATCC 14403, CCUG 43497, CIP 104228, DSM 20302, JCM 11611, NBRC 12144, VKM B-1228.

Sequence accession no. (16S rRNA gene): FJ172667.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) FJ172671.

69. **Corynebacterium striatum** (Chester 1901) Eberson 1918, 22[AL] (*Bacterium striatum* Chester 1901, 171)

stri.a′tum. L. part. neut. adj. *striatum* grooved.

Note: None of the reference strains contained in two major culture collections (ATCC, NCTC) fit the descriptions found in the original publications and the wrong strains appear to have been deposited for this species. Therefore, there is a case for declaring *Corynebacterium striatum* a *nomen dubium* (Rule 56a) exists. However, if a careful search reveals a strain or strains used in the original description agreeing in its characteristics, then a neotype strain can be proposed (Rule 18c). The description here is based primarily on characteristics (now widely accepted for this species) linked to reactions for ATCC 6940 (Coyle et al., 1993a; Funke and Bernard, 2007; Hollis and Weaver, 1981; Leonard et al., 1994; Martinez-Martinez et al., 1995b). The description shown here outlines several biochemical differences from those outlined in the previous edition of this *Manual* (Collins and Cummins, 1986).

Pleomorphic Gram-stain-positive rods, often club-shaped, 0.25–0.5 × 2.0–3.0 µm. Coccoidal forms and long filaments can be found among older cultures. Metachromatic granules may be observed. Colonies may be slow-growing, white, smooth, entire, about 1 mm in diameter after 48 h of incubation at 37°C on sheep blood agar (Collins), but some are creamy, pale-yellow colonies. A strain which caused multiple cases of pneumonia in an ICU was brown pigmented (Leonard et al., 1994). Nonhemolytic, but slight hemolysis may be seen around deep cultures. Nonlipophilic. Facultatively anaerobic. Positive for glucose, fructose, mannose, starch, and dextrin. Variable for galactose and trehalose. Nitrate is reduced, maltose and lactose are negative, and reaction for sucrose is variable. Arabinose, xylose, mannitol, rhamnose, raffinose, and salicin are negative. This is in contrast to a negative reaction for nitrate reduction, a positive reaction for maltose fermentation, and variable reactions for lactose and sucrose as described in the previous version of *Bergey's Manual* (Collins and Cummins, 1986). Urease is not produced, and methyl red is variable (Coyle et al., 1993a). Pyrazinamidase and alkaline phosphatase positive. Esculin not hydrolyzed. Gelatin is described as variable (Collins and Cummins, 1986) or negative (Coyle et al., 1993a). Tyrosine hydrolyzed (Funke and Bernard, 2007; Martinez-Martinez et al., 1995b).

ATCC 6940[T] cell wall contains arabinose and galactose as well as mycolic acids. Menaquinone MK-8(H_2) detected. Cellular fatty acids are like those described for the genus, but tuberculostearic acid is not detected (Bernard et al., 1991). Propionic acid is not detected as a metabolic product of glucose fermentation (Bernard et al., 2002).

Source: human nasopharynx; strains recovered from a variety of human materials, but historically also recovered from the milk of cows with mastitis.

DNA G+C content (mol%): 57.6 (T_m).

Type strain: ATCC 6940, CCUG 27949, CIP 81.15, DSM 20668, JCM 9390, NBRC 15291, NCTC 764.

Sequence accession no. (16S rRNA gene): X81910, X84442.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492267. Multidrug resistant strains have been increasingly documented among patients with *Corynebacterium striatum* infections (Tarr et al., 2003) and it may cause potentially fatal disease among compromised patients (Lee et al., 2005; Otsuka et al., 2006). Person to person transmissions among ICU patients have been documented (Brandenburg et al., 1996; Leonard et al., 1994). Also associated with bovine mastitis (Coyle et al., 1993a).

70. **Corynebacterium suicordis** Vela, Mateos, Collins, Briones, Hutson, Domínguez and Fernández-Garayzábal 2003, 2029[VP]

su.i.cor′dis. L. n. *sus suis* pig; L. n. *cor cordis* heart; N.L. gen. n. *suicordis* of/from pig heart.

Gram-stain-positive rods. Colonies are whitish, circular, smooth, entire, and 1–2 mm in diameter after 48 h incubation at 37°C on sheep blood agar. Facultatively anaerobic. Nonhemolytic. CAMP negative and nonlipophilic. Nitrate is not reduced. Acid is not produced from D-glucose, maltose, lactose, ribose, sucrose, glycogen, mannitol, glycerol, erythritol, D-arabinose, L-arabinose, D-xylose, L-xylose, adonitol, inositol, methyl-β-xyloside, galactose, D-fructose, D-mannose, L-sorbose, rhamnose, methyl-α-D-mannoside, methyl α-D-glucoside, sorbitol, *N*-acetyl-β-glucosamine, amygdalin, arbutin, salicin, cellobiose, melibiose, trehalose, inulin, melezitose, D-raffinose, xylitol, b-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, 5-ketogluconate, or 2-ketogluconate. Urea hydrolyzed, but esculin and gelatin are not. Pyrazinamidase, esterase, ester lipase, alkaline phosphatase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase detected, but pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, lipase, leucine arylamidase, valine arylamidase,

cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-glucosidase, α-mannosidase, and α-fucosidase, are not.

Cell wall contains *meso*-DAP, and corynomycolic acids are present (C_{28}–C_{36}). Cellular fatty acids are consistent with those described for the genus.

Source: the heart, pleural cavity, lymph nodes, and lungs of diseased pigs.

DNA G+C content (mol%): not available.

Type strain: P81/02, CCUG 46963, CECT 5724, JCM 12370.

Sequence accession no. (16S rRNA gene): AJ504424.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EU004068 for CIP 108201.

71. **Corynebacterium sundsvallense** Collins, Bernard, Hutson, Sjödén, Nyberg and Falsen 1999a, 364[VP]

sunds.val.len′se. N.L. neut. adj. *sundsvallense* of or belonging to Sundsvall, Sweden, named after the city from where the bacterium was first isolated.

Gram-stain-positive rods; some branching and bulges/knobs at the ends of some cells may be observed. Colonies are buff or yellowish, opaque, shiny, heaped, and adherent to medium. Nonhemolytic. Nonlipophilic and CAMP negative. Growth possible in 6% NaCl but not in 10% NaCl. Acid produced from fructose, glucose, maltose, and sucrose but not from amygdalin, *N*-acetylglucosamine, galactose, glycogen, lactose, mannitol, ribose, raffinose, salicin, trehalose, or D-xylose. Hippurate is hydrolyzed but esculin, gelatin, and starch are not. Nitrate not reduced. Urease positive and phosphoamidase weakly detected. Variable for α-glucosidase, as 2 strains were positive but 2 are negative (Bernard et al., 2002). Some strains are positive for alkaline phosphatase, leucine arylamidase, pyrazinamidase, ester lipase, and esterase. Acid phosphatase, cystine arylamidase, chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, lipase, α-mannosidase, pyrrolidonyl arylamidase, trypsin, and valine arylamidase are not detected. Type strain has features as described above except weak reactions for pyrazinamidase and alkaline phosphatase are observed and leucine arylamidase, ester lipase, and esterase activities are not detected.

The cell wall contains *meso*-DAP, and mycolic acids are present. Cellular fatty acids consistent with those described for the genus, but tuberculostearic acid is not present. Lactate and succinate but not propionate are major products of glucose fermentation.

Source: human clinical specimens.

DNA G+C content (mol%): 64 (T_m).

Type strain: CCUG 36622, CIP 105936, DSM 44613, JCM 12401.

Sequence accession no. (16S rRNA gene): Y09655.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492268. By 16S rRNA gene sequencing, closely related to (~99.0% identity) to *Corynebacterium thomssenii*, but differs from that species (~90.0% identity) when complete sequences of the *rpoB* gene are compared (Khamis et al., 2004).

72. **Corynebacterium terpenotabidum** Takeuchi, Sakane, Nihira, Yamada and Imai 1999, 228[VP]

ter.pen.o.ta′bi.dum. N.L. n. *terpenum* terpene; L. neut. adj. *tabidum* dissolving; N.L. neut. adj. *terpenotabidum* terpene-dissolving.

Gram-stain-positive irregular rods, 0.5–0.7 × 19–15 μm long in young cultures; some cells are arranged at a V angle. In older cultures, cells are 0.5–0.7 × 0.6–1.0 μm. Colonies on PY-BHI agar are circular, have a rough surface, and are grayish white. Growth occurs under aerobic, but not anaerobic, conditions. Methyl red test negative. Nitrate not reduced to nitrite. Hugh–Leifson's test in glucose oxidation-fermentation (OF) medium is oxidative. Voges–Proskauer test positive. Urease produced, but arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase are not. Tween 80 is hydrolyzed, but starch, gelatin, casein, cellulose, esculin, and tyrosine are not. Fructose, glucose, mannose, lactate, and ethanol are utilized as carbon sources, but galactose, lactose, maltose, sucrose, glycerol, sorbitol, mannitol, inositol, citrate, succinate, malonate, pimelate, *m*-hydroxybenzoate, *p*-hydroxybenzoate, arginine, aspartate, histidine, methylamine, ethylamine, and methanol are not. Thiamin and biotin required for growth. Growth is observed in PY-BHI broth containing 8% but not 10% NaCl.

Cell wall contains *meso*-DAP with arabinose, galactose, and mannose, as major cell-wall sugars. The muramic acids of peptidoglycan occur in the *N*-acetyl form. Menaquinone MK-9(H_2) predominates. Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus, and high levels of tuberculostearic acid are present.

Source: soil.

DNA G+C content (mol%): 67.5 (HPLC).

Type strain: Y -11, CIP 105927, JCM 10555, NBRC 14764, VKM Ac-2071.

Sequence accession no. (16S rRNA gene): AB004730.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492269.

73. **Corynebacterium testudinoris** Collins, Hoyles, Hutson, Foster and Falsen 2001b, 1351[VP]

tes.tu.din.o′ris. L. n. *testudo -inis* tortoise; L. gen. neut. n. *oris* of the mouth; N. L. gen. neut. n. *testudinoris* of the mouth of a tortoise.

Gram-stain-positive rods. Yellow pigmented. Facultatively anaerobic. Nonlipophilic. Acid is produced from glucose, maltose, ribose, and sucrose but not from glycogen, lactose, mannitol, or D-xylose. Activity detected for acid phosphatase (weak), esterase (weak), ester lipase (weak), β-glucosidase, and leucine arylamidase. No activity detected for alkaline phosphatase, cystine arylamidase, chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl- β-glucosaminidase, lipase, α-mannosidase, valine arylamidase, pyrazinamidase, phosphoamidase, pyrrolidonyl arylamidase, urease, or trypsin. α-Glucosidase variable. Esculin is hydrolyzed, but gelatin is not. Nitrate is reduced.

Cell wall contains *meso*-DAP. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not present. Mycolic acids are present (C_{30}–C_{36}).

Source: necrotic lesions in mouth of a tortoise; habitat is unknown.

DNA G+C content (mol%): not available.

Type strain: M935/96/4, CCUG 41823, CIP 106763, DSM 44614, JCM 12108.

Sequence accession no. (16S rRNA gene): AJ295841.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492284.

74. **Corynebacterium thomssenii** Zimmermann, Spröer, Kroppenstedt, Fuchs, Köchel and Funke 1998, 491[VP]

thoms.se′ni.i. N.L. gen. masc. n. *thomssenii* of Thomssen, to honor Reiner Thomssen, a prominent German virologist and medical microbiologist.

Gram-stain-positive diphtheroid-like rods. Colonies of this fastidious slow-growing bacterium are whitish, circular, mucoid, and sticky. After 24 h incubation on Columbia agar supplemented with 5% sheep blood, the colony diameter is less than 0 ± 5 mm. Fermentative. Acid is produced from glucose, maltose, sucrose, D-fructose, D-mannose, trehalose, and 5-keto-gluconate, but not from mannitol, xylose, glycerol, erythritol, arabinose, adonitol, β-methyl-xyloside, L-sorbose, rhamnose, dulcitol, inositol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetyl-β-glucosamine, amygdalin, arbutin, salicin, cellobiose, melibiose, inulin, melezitose, D-raffinose, glycogen, xylitol, β-gentiobiose, D-lyxose, L-arabitol, gluconate, and 2-keto-gluconate. Pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, leucine arylamidase, cystine arylamidase, acid phosphatase, and *N*-acetyl-β-glucosaminidase present, but lipase, valine arylamidase, chymotrypsin, α-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, α-mannosidase, and α-fucosidase are not. One isolate was *N*-acetyl-β-glucosamine negative (Bernard et al., 2002). Urea hydrolyzed, but nitrate not reduced. Esculin hydrolysis negative. Nonlipophilic and CAMP reaction negative. DNase activity observed after 48 h. Tyrosine not hydrolyzed.

Cell wall contains arabinose and galactose as well as *meso*-DAP. Corynemycolates (C_{32}–C_{36}) are present. Cellular fatty acids are consistent with those described for the genus. Polar lipids are composed of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. MK-8(H2) and MK-9(H2) found; small amounts of MK-10(H2) also found. Propionic acid not detected as a fermentation product (Bernard et al., 2002).

Source: pleural fluid from a patient with chronic renal failure, stroke, and pneumonia and from air (Bernard et al., 2002).

DNA G+C content (mol%): not available.

Type strain: CCUG 38516, CIP 105597, DSM 44276, JCM 12109.

Sequence accession no. (16S rRNA gene): AF010474.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492270. By 16S rRNA gene sequencing, closely related to (~99.0% identity) *Corynebacterium sundsvallense*, but differs from that species (~90.0% identity) when sequences of the *rpoB* gene are compared (Khamis et al., 2004).

75. **Corynebacterium timonense** Merhej, Falsen, Raoult and Roux 2009, 1956[VP]

ti.mo.nen′se. N.L. neut. adj. *timonense* of or pertaining to Hôpital de la Timone, the name of a hospital in Marseille France where the type strain was isolated.

Gram-stain-positive typically club-shaped rods that occur as single cells, in pairs, or in small clusters. Rods are 0.6–2.1 × 0.4–0.6 µm after 48 h growth in TSB medium (as determined by electron microscopy). After 24 h growth on sheep blood agar at 37°C, surface colonies are circular, yellow, shiny, and 1–2 mm in diameter. Capable of aerobic and anaerobic growth. Temperature range for growth is 25–50°C (optimum, 37°C). With the API Coryne system, acid produced from D-glucose and D-ribose, but not from D-xylose, D-mannitol, maltose, D-lactose, sucrose, or glycogen. Nitrate not reduced. Esculin is weakly hydrolyzed, but urea and gelatin are not. With API Coryne and API ZYM strips, positive for pyrazinamidase, alkaline phosphatase, esterase, esterase lipase, lipase (weakly), leucine arylamidase, valine arylamidase, and acid phosphatase, but negative for pyrrolidonyl arylamidase, cystine arylamidase, trypsin, achymotrypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase.

Cellular fatty acids are found to be consistent with those described for the genus, but tuberculostearic acid is not detected. Other chemotaxonomic properties were not extant.

Source: multiple blood cultures of a septic patient post-surgically after a pacemaker had been implanted.

DNA G+C content (mol%): not available.

Type strain: 5401744, CCUG 53856, CIP 109424, CSUR P20.

Sequence accession no. (16S rRNA gene): EF217055.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) EF217058.

76. **Corynebacterium tuberculostearicum** Feurer, Clermont, Bimet, Candréa, Jackson, Glaser, Bizet and Dauga 2004, 1059[VP] ("*Corynebacterium tuberculostearicum*" Brown, Lanéelle, Asselineau and Barksdale 1984, 251)

tu.ber.cu.lo.ste.a′ri.cum. N.L. neut. adj. *tuberculostearicum* pertaining to tuberculostearic acid which is contained in the cells.

Pleomorphic Gram-stain-positive rods which can develop coccoid forms in stationary cultures. Colonies on trypto casein soy agar supplemented with Tween 80 are circular, convex, glistening, and 1 mm in diameter. Aerobic to facultatively anaerobic. Lipophilic. Acid is produced from galactose, glucose, glycerol, fructose, mannose, ribose, and 5-ketogluconate but not from mannitol, glycogen, starch, sorbitol, lactose, inulin, or xylose. Production of acid from trehalose, maltose, gluconate, sucrose, and *N*-acetylglucosamine is variable. Urea, esculin and gelatin are not hydrolyzed. Presence of nitrate reductase is variable. DNase is absent. Esterase and naphthol-AS-BI-phosphohydrolase activities are detected, and esterase lipase, leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, and alkaline phosphatase production is variable. No activity is detected for α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, α-fucosidase, lipase (C14), trypsin, or α-chymotrypsin. The following substrates are utilized in 2 or 4 d: D-glucose, sucrose, D-ribose, glycerol, L-malate, 2-ketogluconate, succinate, fumarate, L-aspartate, L-glutamate, L-proline, and L -serine. The following substrates are not utilized in 6 d: caprate, citrate, and DL-glycerate. The type strain has all the

properties given for the species except that it also assimilates D-mannose.

Corynemycolic acids are present, and the Cellular fatty acids are consistent with those described for the genus as well as for CDC group G (Bernard et al., 1991); strains usually contain small volumes of tuberculostearic acid.

Source: a case of lepromatous leprosy in the Phillipines and a wide variety of human clinical specimens.

DNA G+C content (mol%): not available.

Type strain: Medalle X, LDC-20, ATCC 35692, CCUG 45418, CIP 107291.

Sequence accession no. (16S rRNA gene): AJ438050, X84247.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) AY581869.

ATCC 35529, listed as the type strain of *Corynebacterium tuberculostearicum* sp. nov., was deaccessioned by the ATCC and replaced with ATCC 35692 (Feurer et al., 2005).

By 16S rRNA gene sequencing, some strains previously identified as CDC group G or as "*Corynebacterium pseudogenitalium*", including CIP 106714, are closely related (have >99% identity by 16S rRNA gene sequencing) to *Corynebacterium tuberculostearicum* (K. Bernard and G. Funke, personal communication). In 1984, "*Corynebacterium tuberculostearicum*" was first described as a novel species but not validly named, with the type strain being recovered from bone marrow of a patient with lepromatous leprosy in the Philippines (Brown et al., 1984). This taxon was re-evaluated, with additional clinical strains described from inguinal node, lymph node, blood culture, urethra, skin, peritoneum, urine, and a healthy urogenital tract. Also recovered from tuna and an industrial environment.

77. **Corynebacterium tuscaniense** corrig. Riegel, Creti, Mattei, Nieri and von Hunolstein 2006b, 2025[VP] (Effective publication: Riegel, Creti, Mattei, Nieri and von Hunolstein 2006a, 311.)

tus.ca.ni.en′se. L. neut. adj. *tuscaniense* pertaining to *Tuscania*, Latin name of the Italian region, Tuscany, where the type strain was isolated.

Note: "Corynebacterium tuscaniae" epithet was corrected to *Corynebacterium tuscaniense* (Euzéby, 2006).

Gram-stain-positive rods. Colonies are whitish, circular with entire edges, nonhemolytic, grow aerobically and in the presence of a 5% CO_2-enriched atmosphere. Acid produced from glucose and maltose but not from ribose, xylose, mannitol, lactose, sucrose, or glycogen. Nitrate not reduced. Produces pyrazinamidase and alkaline phosphatase but not pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, α-glucosidase, β-*N*-acetyl-glucosaminidase, urease, or esterase activity. Hydrolyzes hippurate but not tyrosine, gelatin, or esculin. CAMP test and reverse CAMP test negative.

Contains mycolic acids with short chain lengths (C_{26}–C_{36}), but other chemotaxonomic features such as Cellular fatty acids not extant.

Source: the blood of a patient with endocarditis.

DNA G+C content (mol%): not available.

Type strain: ATCC BAA-1141, CCUG 51321, ISS-5309, JCM 15294.

Sequence accession no. (16S rRNA gene): AY677186.

Further comments: additional GenBank accession numbers include (partial *rpoB* gene) FJ268581.

78. **Corynebacterium ulcerans** (*ex* Gilbert and Stewart 1927) Riegel, Ruimy, De Briel, Prévost, Jehl, Christen and Monteil 1995b, 619[VP] (Effective publication: Riegel, Ruimy, De Briel, Prévost, Jehl, Christen and Monteil 1995c, 275.) ("*Corynebacterium ulcerans*" Gilbert and Stewart 1927)

ul′ce.rans. L. part. adj. *ulcerans* making sore, causing to ulcerate.

Gram-stain-positive pleomorphic rods arranged in palisades or V-shaped forms. May contain metachromatic granules. Facultatively anaerobic. Colonies (1–2 mm in diameter) on 5% sheep blood agar are gray-white, exhibit a light hemolysis, and may have a dry and waxy consistency. Circular, slightly convex with an entire margin. Nitrate is not reduced to nitrite. Acid is produced from D-glucose, glycogen, maltose, and fructose but not from lactose, sucrose, D-xylose, and trehalose. Some strains produce acid from mannitol. Starch, DNA, and urea are degraded but tyrosine is not. Gelatin is hydrolyzed at 25°C and at 37°C by some strains. Esculin is not hydrolyzed. Methyl red is positive, and acetoin is not produced. Some strains grow in 6.5% NaCl. Hippurate is hydrolyzed. Alkaline phosphatase and α-glucosidase are produced, but pyrazinamidase, pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, *N*-acetyl-β-glucosaminidase are not. As sole carbon sources, cells utilize glucose, arabinose, mannose, maltose and malate, with utilization of mannitol and gluconate occurring variably. Acetate, lactate, propionate, caprate, adipate, and phenylacetate are not ulitilzed. Fermentation of glycogen and starch plus urease is unique among species described here. The type strain is as described for the species but ferments mannitol and not gluconate.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose. Short chain length mycolic acids (C_{26}–C_{36}) are present. Cellular fatty acids are consistent with those described for the genus, including characteristically (for *Corynebacterium diphtheriae*, *Corynebacterium pseudotuberculosis*, and *Corynebacterium ulcerans*), a large volume of a $C_{16:1}$ isomer (Bernard et al., 1991). Propionic acid is produced as a metabolic product (Bernard et al., 2002).

Source: animals and humans. Infection of farm animals or their milk can result in the transmission of infection to humans. Infections from companion pets have been documented to be transferred to and cause disease in humans (De Zoysa et al., 2005b; Hogg et al., 2009).

DNA G+C content (mol%): 53 (T_m).

Type strain: ATCC 51799, CCUG 2708, CIP 106504, DSM 46325, JCM 10387, NCTC 7910.

Sequence accession no. (16S rRNA gene): X84256.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492271. *Corynebacterium pseudotuberculosis* and *Corynebacterium ulcerans* are the only *Corynebacterium* species to produce phospholipase D (PLD), with expression of the *pld* gene product being detected by inhibition of the CAMP reaction (Barksdale et al., 1981) or by PCR detection of the gene (Pacheco et al., 2007). Like *Corynebacterium diphtheriae* and *Corynebacterium pseudotuberculosis*, *Corynebacterium ulcerans* produces cystinase, as demonstrated by production of brown colonies and haloes when grown on modified Tinsdale medium, and fails to produce pyrazinamidase (PYRa). By 16S rRNA gene sequencing,

this species is most closely related to (>99% identity with) *Corynebacterium pseudotuberculosis* and to (>97% identity with) *Corynebacterium diphtheriae* but can be readily distinguished when *rpoB* gene sequences are compared (Khamis et al., 2004). *Corynebacterium ulcerans* is able to harbor the bacteriophage which bears diphtheria toxin gene and also express the toxin, causing diphtherial like disease. If recovered from pseudomembranous materials, patient must be treated as for diphtheria.

79. **Corynebacterium ulceribovis** Yassin 2009, 36[VP]

ul.ce.ri.bo'vis. L. n. *ulcus*, *-eris* ulcer; L. n. *bos*, *bovis* a cow a bull; N.L. gen. n. *ulceribovis* of an ulcer of a cow.

Gram-stain-positive rods. Colonies are creamy, circular, smooth, entire, and 2–4 mm in diameter after 48 h incubation at 37°C on Columbia agar supplemented with 5% sheep blood. Facultatively anaerobic. Colonies are nonhemolytic. Hippurate and Tween 80 are hydrolyzed, but esculin, gelatin, and urea are not. Activity is detected for acid phosphatase, alkaline phosphatase, esterase lipase, leucine arylamidase, pyrazinamidase, and naphthol-AS-BI-phosphohydrolase but not for arginine dihydrolase, chymotrypsin, cysteine arylamidase, esterase, α-fucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, lipase, α-mannosidase, pyrrolidonyl arylamidase, trypsin, or valine arylamidase. Nitrate is not reduced. Acetoin production is positive.

Corynemycolic acids are present. Cellular fatty acids are consistent with those described for the genus, but tuberculostearic acid is not detected.

Source: the skin of the udder of a cow with a profound ulceration in Schleswig Holstein, Germany.

DNA G+C content (mol%): not available.

Type strain: IMMIB L-1395, CCUG 55727, DSM 45146.

Sequence accession no. (16S rRNA gene): AM922112.

80. **Corynebacterium urealyticum** Pitcher, Soto, Soriano and Valero-Guillén 1992, 180[VP]

u.re.a.ly'ti.cum. N.L. fem. n. *urea* urea; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *urealyticum* urea dissolving.

Gram-stain-positive rods which may become coccoidal after prolonged culture, are 0.5–1 μm arranged in palisades and V shapes, with no tendency to branch. Bacteria grow on blood agar as pinpoint colonies after 48 h of incubation at 25, 37, and 42°C. Colonies are whitish, opaque, smooth, convex, and nonhemolytic. Respiratory metabolism, i.e. does not grow on blood agar incubated anaerobically for 48 h or on MacConkey agar. Nonreactive with usual sugars, i.e. acid is not produced from glucose, sucrose, maltose, mannitol, xylose, ribose, L-arabinose, sorbitol, lactose, trehalose, inulin, raffinose, starch, and glycogen. Does not hydrolyze gelatin or esculin. Nitrate is not reduced. Does not degrade DNA. Possesses strong urease activity. Hydrolyzes Tween 80. Lipophilic, i.e. growth is stimulated by Tween 80. Some strains hydrolyze hippurate or give a positive Voges–Proskauer reaction.

Cell wall contains *meso*-DAP and the sugars arabinose and galactose. Cellular fatty acids are consistent with those described for the genus and 10-methyloctadecanoic (tuberculostearic) acid is detected. Mycolic acids (C_{26}–C_{36}) are present. Menaquinone MK-9(H_2) is found. Contains diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Propionic acid is not produced by anaerobic metabolism of glucose.

Source: urine, particularly in humans with lithiasis and alkaline-encrusted cystitis as complications, but also recovered from other normally sterile sites and human skin. Occasionally recovered from animals with urosepsis (Bailiff et al., 2005).

DNA G+C content (mol%): 61–62 (T_m; Pitcher et al., 1992), 65–66 (HPLC, Riegel et al., 1992), and 64.2 (complete genome sequence, Tauch et al., 2008b).

Type strain: ATCC 43042, CCUG 18158, CIP 103524, DSM 7109, JCM 10395, LMG 19041, NCTC 12011.

Sequence accession no. (16S rRNA gene): X81913, X84439.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492275. *Corynebacterium urealyticum* Pitcher et al. 1992 was previously known as CDC coryneform group D-2 (Riegel et al., 1992). The complete genome of *Corynebacterium urealyticum* strain DSM 7109T, with 2,369,219 bp has been deposited in GenBank under accession no. NC_010545 (Tauch et al., 2008b). Clinical features with respect to data inferred from complete genomic analyses have been reviewed (Soriano and Tauch, 2008). Strains can be multidrug resistant (Fernandez-Roblas et al., 2009; Philippon and Bimet, 1990) and nosocomially acquired (Famularo et al., 2008).

81. **Corynebacterium ureicelerivorans** Yassin 2007, 1202[VP]

u.re.i.ce.le.ri.vo'rans. N.L. fem. n. *urea* urea; L. adj. *celer*, *-eris* fast; L. part. adj. *vorans* devouring; N.L. part. adj. *ureicelerivorans* fast urea-devouring, referring to the rapid utilization of urea.

Gram-stain-positive rods. Colonies are creamy, circular, dry, and approximately 0.1–0.3 mm in diameter on Columbia blood agar after 48 h incubation at 37°C. Colonies are nonhemolytic. Facultatively anaerobic. Lipophilic. Urea rapidly positive (reaction in approximately 60 sec). Hippurate hydrolyzed, but esculin and gelatin are not. Nitrate not reduced. Acid produced from glucose. Weak acid production is observed from ribose and D-xylose in the API Coryne and API 20 Strep systems after 3 d. Acid is not produced from L-arabinose, glycerol, glycogen, inulin, lactose, maltose, mannitol, sorbitol, sucrose, trehalose, or D-raffinose. Alkaline and acid phosphatases, ester lipase, naphthol- AS-BI-phosphohydrolase, leucine arylamidase, pyrrolidonyl arylamidase, and pyrazinamidase are detected, but arginine dihydrolase, esterase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, chymotrypsin, trypsin, valine arylamidase, cystine arylamidase, and leucine arylamidase, are not. Acetoin produced.

Mycolic acids are present. Cellular fatty acids are consistent with those described for the genus, and tuberculostearic acid is present.

Source: blood culture of patient with septicemia (Yassin, 2007), but also recovered from other normally sterile body fluids (Fernandez-Natal et al., 2009).

DNA G+C content (mol%): not available.

Type strain: IMMID RIV-2301, CCUG 53377, DSM 45051, JCM 15295.

Sequence accession no. (16S rRNA gene): AM397636.

82. **Corynebacterium variabile** corrig. (Müller 1961) Collins 1987a, 287 [VP] (*Arthrobacter variabilis* Müller 1961, 524)
Note: original spelling of the specific epithet, *Corynebacterium variabilis* (*sic*), was later corrected to *Corynebacterium variabile*.

va.ri.a′bi.le. L. neut. adj. *variabile* changeable, variable.

Gram-stain-positive rod-shaped cells (0.8–1.1 × 1.4–3.5 μm), irregularly shaped (club-shaped or tapered), and occurring singly, in pairs with typical V forms, or clumps; ovoid forms occur in older cultures. Colonies are small (~2–4 mm), circular (sometimes irregular), convex, and gray-white (occasionally slight pink) with a dry appearance. Optimum temperature is 25–30°C. Grows in 7% NaCl. Strictly aerobic. Acetate, propionate, capronate, 4-aminobutyrate, caprylate, succinate, DL-malate, levulinate, and some other compounds may be used as sole carbon sources. Xanthine, tyrosine, and starch are not hydrolyzed.

Cell wall contains *meso*-DAP, with the glycan moiety containing only acetyl residues. The cell wall also contains an arabinogalactan polymer. Short-chain mycolic acids (C_{30}–C_{36} carbon atoms) are present. Cellular fatty acids are consistent with those described for the genus, including high levels of tuberculostearic acid. The major menaquinones are MK-9(H_2) and MK-8(H_2).

Source: the environment and the surface of soft cheese (Gelsomino et al., 2005).

DNA G+C content (mol%): 65 (T_m).

Type strain: ATCC 15753, CCUG 45246, CIP 102112, DSM 20132, HAMBI 1872, JCM 2154, NBRC 15286, NCIMB 9455, NRRL B-4201, VKM Ac-1122.

Sequence accession no. (16S rRNA gene): AJ222815.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492272. *Arthrobacter variabilis* Müller 1961[AL] *and Caseobacter polymorphus* Crombach 1978[AL] are both considered as later synonyms of *Corynebacterium variabile* (Collins 1987a, 1989). *Corynebacterium moorparkense* (Brennan et al., 2001) is also considered as a later heterotypic synonym of *Corynebacterium variabile* corrig. (Müller 1961) Collins 1987a, 287 (Gelsomino, Vancanneyt, Snauwaert, Vandemeulebroecke, Hoste, Cogan and Swings 2005, 1129).

83. **Corynebacterium vitaeruminis** corrig. (Bechdel et al. 1928) Lanéelle, Asselineau, Welby, Norgard, Imaeda, Pollice and Barksdale 1980, 544[VP] ["*Flavobacterium vitarumen*" Bechdel, Honeywell, Dutcher and Knutsen 1928, 234; *Brevibacterium vitarumen* (Bechdel et al. 1928) Breed, Murray and Smith 1957, 495]

vi.ta.e.ru.mi′nis. L. n. *vitae* life; L. n. *rumen -inis* throat, gullet, rumen; N.L. gen. n. *vitaeruminis* of rumen life.

Note: spelling of the epithet, *vitarumen* (*sic*), was corrected by Trüper and De'Clari 1997, 908.

(Some information from this description is based on that of Collins and Cummins, 1986.)

Pleomorphic Gram-stain-positive rod-shaped bacteria wth moderately tapered ends. May contain metachromatic granules when grown on phosphate rich media. Lemon yellow colonies on Loeffler slants with raised, smooth, butyrous yellow colonies on chocolate agar, and black colonies with chocolate agar containing 0.03% tellurite. Facultatively anaerobic. Positive for glucose, fructose, galactose, mannose, maltose, sucrose, salicin, and trehalose. Negative for glycerol, inositol, mannitol, lactose, and starch. Esculin hydrolyzed, nitrate is reduced to nitrite, acetoin and urease are produced, and methyl red is positive. Pyrazinamidase positive, but phosphatase negative. Hippurate and gelatin are not hydrolyzed.

Cell wall contains *meso*-DAP and the sugars arabionse and galactose. Short-chain corynemycolates and menaquinone MK-8(H_2) are present.

Source: the rumen of a cow.

DNA G+C content (mol%): 64.8 (T_m).

Type strain: ATCC 10234, CCUG 28792, CIP 82.7, DSM 20294, JCM 1323, NBRC 12143, NCIMB 9291, VKM B-1211.

Sequence accession no. (16S rRNA gene): AY438066.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492273.

84. **Corynebacterium xerosis** (Lehmann and Neumann 1896) Lehmann and Neumann 1899, 385[AL] (*Bacillus xerosis* Lehmann and Neumann 1896, 361)

xe.ro′sis. N.L. gen. n. *xerosis* (from Gr. adj. *xeros* dry) of xerosis.

Note: description below is based on ATCC 373[T], as some commercially available reference strains were shown to be misidentified after contemporary characterization methods were applied, with some being identifiable as *Corynebacterium striatum* (Coyle et al., 1993b) or *Corynebacterium amycolatum* (Funke et al., 1996a; Wauters et al., 1996).

Gram-stain-positive rods with irregular staining, barred rods with occasional granules and club forms. Colonies are small, circular ~0.2–1.0 mm in diameter after growth on blood agar at 24 h. Colonies dryish and slightly yellow colored (Coyle et al., 1993b). In broth, forms a large pellicle over a clear broth, with settled clumps observed. Nonhemolytic. Not lipophilic. Facultatively anaerobic. Grows anaerobically. CAMP reaction negative. Nitrate either reduced or considered as variable (Funke and Bernard, 2007). Glucose, maltose, and sucrose fermented, but xylose and mannitol are not (Coyle et al., 1993b; Funke and Bernard, 2007). Also described as usually being negative for arabinose, rhamnose, lactose, trehalose, raffinose, dextrin, and starch, but positive for salicin (Collins and Cummins, 1986). ATCC 373[T] has been described as containing cell-wall sugars of arabinose, galactose, and glucose with smaller amounts of rhamnose. Corynemycolates are present. Cellular fatty acids consistent with those described for the genus are present, but tuberculostearic acid is not detected (Bernard et al., 1991). Propionic acid is not detected as a fermentation product (Funke et al., 1996a).

Source: the ear discharge of a child.

DNA G+C content (mol%): 67.3 (method unknown).

Type strain: ATCC 373, CCUG 27544, CIP 100653, DSM 20743, JCM 1971, NBRC 16721, NCTC 11861.

Sequence accession no. (16S rRNA gene): X81914, X84446.

Further comments: additional GenBank accession numbers include (complete *rpoB* gene) AY492233. Once described as a relatively common human pathogen, *Corynebacterium xerosis* infections are now considered to occur only very rarely, and diseases attributed to this agent should be considered as definitive only if polyphasic, including genetic identification methods, are used. In particular, older publications implicating *Corynebacterium xerosis* as a pathogen, especially those where microbiological descriptions were based solely on phenotypic testing, may be actually describing disease caused by *Corynebacterium amycolatum* Funke et al. 1996a or other *Corynebacterium* species. Reference strains other than ATCC 373^T designated *Corynebacterium xerosis* must be carefully evaluated prior to use in research. ATCC 7711, with a DNA G+C content of 68.5 mol% (Collins and Cummins, 1986), has been found to be closely related to ATCC 373^T by 16SrRNA and partial *rpoB* gene sequence analyses, but NCTC 7243 is closely related to (>99% identity with) *Corynebacterium amycolatum* (K. Bernard, personal communication). *Corynebacterium xerosis* cannot be easily discerned from *Corynebacterium freneyi* and *Corynebacterium hansenii* by 16S rRNA, *rpoB*, or 16S–23S spacer region gene sequence analyses; these are best separated by DNA–DNA hybridization or phenotypic means (Renaud et al., 2007).

Genus II. **Turicella** Funke, Stubbs, Altwegg, Carlotti and Collins 1994, 272^{VP}

Hans-Jürgen Busse

Tu.ri.cel′la. *Turicum* proper name Turicum; L. fem. dim. suff. *-ella*; N.L. fem. dim. n. *Turicella* pertaining to Turicum, the Latin name of Zurich, Switzerland, where the first isolates were collected.

Cells are Gram-stain positive, nonmotile, nonsporeforming diphtheroids that occur as single cells or are arranged in V-shaped forms or palisades. Colonies are circular, convex, and creamy in color and range from 1.0–2.0 mm in diameter after 48 h of incubation at 37°C on sheep blood agar. **Catalase positive and oxidase negative**. **Metabolism is respiratory**. **Cell wall contains *meso*-diaminopimelic acid, arabinose, and galactose**. **Mycolic acids are not produced**. **The principal menaquinones** are **MK-10 and MK-11**. Major fatty acids are **$C_{16:0}$, $C_{18:0}$, and $C_{18:1}$; tuberculostearic acid is produced**.

DNA G+C content (mol%): 65–72.

Type species: **Turicella otitidis** Funke, Stubbs, Altwegg, Carlotti and Collins 1994, 272^{VP}.

Further descriptive information

In (1993) Simonet et al. reported on the isolation and characterization of facultatively anaerobic, Gram-stain-positive bacteria from middle ear fluid of children suffering from acute otitis media. In routine diagnosis, 16 isolates shared numerous traits with *Corynebacterium afermentans* subsp. *afermentans* (CDC *Corynebacterium* group ANF-1; Riegel et al., 1993b). Like *Corynebacterium afermentans* subsp. *afermentans*, these isolates grew well under aerobic and microaerobic conditions and weakly under anaerobic conditions, but showed clear differences in colony morphology and, unlike *Corynebacterium afermentans*, lacked mycolic acid. Despite the presence of *meso*-diaminopimelic acid and arabinogalactan in the cell wall, the authors concluded that the 16 isolates could not be members of the genus *Corynebacterium* and tentatively designated them ANF-1 like. In the following year, Funke et al. (1994) reported on the classification of three Gram-stain-positive, coryneform rods which had been isolated from middle ear fluids from 1–5-year-old patients treated for otitis media in Zürich, Switzerland. The three strains shared 100% identity in a 500-base fragment of the 16S rRNA gene and the selected reference strain exhibited in almost complete 16S rRNA gene highest sequence similarity with species of the genus *Corynebacterium* (90.7–91.6%). The strain was shown to contain a cell wall with *meso*-diaminopimelic acid, arabinose, and galactose, but, unlike the majority of *Corynebacterium* species, it lacked mycolic acids and exhibited a completely unsaturated quinone system with the major compounds MK-10 and MK-11. Funke et al. (1994), mainly on the basis of phylogenetic distinctness, lack of mycolic acids, and the quinone system, concluded that these strains were representatives of a novel genus and novel species for which they proposed the genus *Turicella* with the single species *Turicella otitidis*. Since then, no new species has been added to the genus.

Phylogenetically, *Turicella otidis* has been reported to occupy a separate line of descent within the 16S rRNA *Corynebacterium* gene tree (Funke et al., 1994; Pascual et al., 1995; Ruimy et al., 1995); *rpoB* sequence data are in line with these findings (Khamis et al., 2004). However, 16S rRNA gene sequence similarities below 92.0% (by applying FASTA; Pearson and Lipman, 1988) and not higher than 93.1% with recognized *Corynebacterium* species by applying EzTaxon (Chun et al., 2007) support separation from *Corynebacterium*. Interestingly, in gene banks the partial 16S rRNA gene sequence (888 nucleotides; accession number Z33617) of a single strain (CDC group ANF-1-like ATCC 51308) shows a high similarity (98.1%) with the type of *Turicella otitidis*, suggesting it originated from a *Turicella* species.

A culture-independent approach showed that *Turicella otitidis*-like organisms were among the most abundant colonizers of the human ear canal of healthy individuals (Frank et al., 2003; erroneously these authors designated the reference species *Corynebacterium otitidis*). These cloned 16S rRNA gene sequences exhibited 97.1–99.6% with *Turicella otitidis* indicating that they originated from *Turicella otitidis*-like organisms. In another study, the human microbial skin community was analyzed on the basis of cloned 16S rRNA gene sequences (Grice et al., 2009). These authors detected *Turicella otitidis*-like sequences (>98% similarity) predominantly in samples from the external auditory canal but also from the manubrium, elbow, and retroauricular crease. Other *Turicella otitidis*-like sequences deposited in gene banks were recovered from skin samples of the antecubital and popliteal fossa, volar forearm, and also from floor and mattress dusts. Another *Turicella otitidis*

strain with a similar 16S rRNA gene sequence (>99% similarity in 551 nucleotides) was identified in a clone library from a deep-sea sediment core (Stach et al., 2003).

Lack of mycolic acids distinguishes *Turicella otitidis* from most members of the order *Corynebacteriales*, and only few species of the genus *Corynebacterium* have been reported to lack mycolic acids. These include *Corynebacterium amycolatum* (Collins et al., 1988a), *Corynebacterium atypicum* (Hall et al., 2003), *Corynebacterium kroppenstedtii* (Collins et al., 1998), and *Corynebacterium ciconiae* (Fernández-Garayzábal et al., 2004). Neither 16S rRNA gene sequences nor *rpoB* sequences suggest a closer relationship between *Turicella otitidis* and the mycolateless *Corynebacterium* species than with mycolic acid containing species. Quinone systems with completely unsaturated menaquinones are rare and the presence of menaquinones MK-10 and MK-11 is so far unique within the family *Corynebacteriaceae*. The lipoglycan of *Turicella otitidis* is a truncated lipoarabinomannan consisting of a mannosyl phosphatidylinositol anchor unit which carries an (1→6)-linked mannan core and substituted terminal-arabinosyl-branches (Gilleron et al., 2005).

However, other taxa classified in the order *Corynebacteriales* lack mycolic acids and have a quinone system with completely unsaturated menaquinones, such as *Hoyosella altamirensis* (MK-8; Jurado et al., 2009) and *Amycolicicoccus subflavus* (MK-8; Wang et al., 2010). In addition, *Tsukamurella* species contain completely unsaturated menaquinones with nine isoprenoic units in the side chain (MK-9) though they do contain mycolic acids (Collins et al., 1988c; Yassin et al., 1996, 1997).

For treatment of *Turicella otitidis* infections, linezolid, teicoplanin, and vancomycin are usually effective and often *Turicella otitidis* strains also tend to show low MICs to β-lactams (ampicillin, imipenem, penicillin G), fluoroquinolones (ciprofloxacin, levofloxacin), macrolides (azithromycin, erythromycin, miocamycin), chloramphenicol, clindamycin, gentamicin, rifampin, and tetracycline (Funke et al., 1996b; Gómez-Garcés et al., 2007). Troxler et al. (2001) showed that *Turicella otitidis* strains are sensitive to numerous antibiotics though a significant proportion of *Turicella otitidis* strains show high MICs against macrolides and clindamycin (Funke et al., 1996b). Cross-resistance between erythromycin and clindamycin is frequently observed in *Turicella otitidis* (Funke et al., 1996b). It seems likely that resistance to azithromycin, clarithromycin, erythromycin, and spiramycin is conferred by mutations in the 23S rRNA gene at position 2058 and/or 2059 (*Escherichia coli* numbering), whereas these mutations do not influence the susceptibility to pristinamycin (Boumghar-Bourtchai et al., 2009).

Pathogenicity. *Turicella otitidis* is frequently isolated from children suffering from different variants of otitis media. Its role in this disease is controversial as it is also isolated from the external auditory canal of healthy children suggesting that it is part of the normal flora, though it seems that the frequency of *Turicella otitidis* is higher in patients with otitis media with effusions than in controls (Funke et al., 1994; Gómez-Garcés et al., 2004; Holzmann et al., 2002; Pierot et al., 2005). However, *Turicella otitidis* has also been found to be associated with otitis externa, mastoiditis, febrile bacteremia, and to be the causative agent of an auricolar and a cervical abscess (Dana et al., 2001; Fernández Pérez et al., 1999; Jeziorski et al., 2009; Loïez et al., 2002; Poulter and Hinnebusch, 2005; Reynolds et al., 2001). Hence, *Turicella otitidis* must be considered at least to be an opportunistic pathogen.

Enrichment and isolation procedures

Susceptibility testing of *Turicella otitidis* (Troxler et al., 2001) has shown that this species exhibits natural resistance to aztreonam, cotrimoxazole, fosfomycin, nitrofurantoin, pipemidic acid, and sulfamethoxazole, hence, these antibiotics might be useful for selective enrichment. *Turicella otitidis* can be cultivated on Columbia agar base supplemented with 5% sheep blood in a 5% CO_2 atmosphere (Funke et al., 1994), trypticase soy agar with 5% sheep blood, chocolate agar supplemented with pyridoxal in a 5% CO_2 atmosphere (Poulter and Hinnebusch, 2005), cooked-meat broth (Reynolds et al., 2001), and brain-heart infusion broth supplemented with 2% yeast extract (Gilleron et al., 2005).

Differentiation of the genus *Turicella* from other genera

Identification of novel *Turicella* strains other than *Turicella otitidis* is hampered by the fact, that so far only one species has been described; hence it is not clear which phenotypic traits are shared by other representatives of the genus. Species of the neighboring genus *Corynebacterium* show some variability in phenotypic traits usually considered to be stable within a genus, including the quinone system and the presence of mycolic acids. Hence, it is possible that undescribed species of the genus *Turicella* may not lack mycolic acids or may exhibit a quinone system different from that found in *Turicella otitidis*. Novel *Turicella* strains can be reliably differentitated from *Corynebacterium* by high similarities in the sequences of the 16S rRNA gene and *rpoB* since *Turicella otitidis* shares <94% and <84% similarity, respectively with species of the genus *Corynebacterium* and even less with species of other genera of the *Corynebacteriales*. Detection of a quinone system with completely unsaturated menaquinones with ten and eleven isoprenoic units in the side chain (MK-10, MK-11) and lack of mycolic acids distinguishes *Turicella otitidis* from *Corynebacterium* species. Furthermore, the non-fermentative metabolism is another characteristic distinguishing *Turicella otitidis* from the majority of *Corynebacterium* species. Traits useful for the differentiation of *Turicella otitidis* from *Corynebacterium auris* (CDC coryneform group ANF-1-like bacteria) and *Corynebacterium afermentans* (CDC coryneform ANF-1 bacteria) are listed in Table 33.

TABLE 33. Differentiation of *Turicella otitidis* from two other absolute non-fermenter species, *Corynebacterium afermentans* and *Corynebacterium aurum*[a,b]

	T. otitidis	*C. afermentans*	*C. aurum*

Taxonomic comments

Many published phylogenetic trees indicate that the monospecific genus *Turicella* forms a deeply branching lineage within and not separate from the clade comprising the species of the genus *Corynebacterium* (Brennan et al., 2001; Funke et al., 1997e, 1998c; Jurado et al., 2009; Ludwig et al., 2009a; Renaud et al., 2001; Riegel et al., 1995e, 1997b, 2004; Ruimy et al., 1995; Wattiau et al., 2000). Hence, the phylogenetic placement of *Turicella otitidis* among *Corynebacterium* species creates a non-monophyletic genus *Corynebacterium* which in the taxonomy of today is undesirable. However, recognition of the genus *Turicella* is supported by a quinone system (MK-10, MK-11) which is not found in *Corynebacterium* species and by the lack of mycolic acids which distinguishes the species from the vast majority of *Corynebacterium* species.

List of species of the genus *Turicella*

1. **Turicella otitidis** Funke, Stubbs, Altwegg, Carlotti and Collins 1994, 272[VP]

o.ti′ti.dis. Gr. n. *ous*, *otos* ear; N.L. suff. *-itis*, *-idis* suffix used in names of inflammations; N.L. gen. n. *otitidis* of inflammation of the ear.

Cells are Gram-stain positive, nonmotile, nonsporeforming diphtheroids which occur as single cells or are arranged in V-shaped forms or palisades. Colonies are circular, convex, and creamy in color. Colony diameters range from 1.0–2.0 mm after 48 h of incubation at 37°C on sheep blood agar. Growth is visible in the presence of 6.5% NaC1. Catalase positive and oxidase negative. Metabolism is respiratory. Acid is not produced from D-glucose, glycogen, lactose, maltose, D-mannitol, ribose, sucrose, and D-xylose or on triple-sugar iron agar. Nitrate is not reduced. Does not produce indole or hydrolyze urea or esculin. Growth is visible in the presence of 6.5% NaCl. Acid phosphatase, alkaline phosphatase, and leucine arylamidase are produced. The cell wall contains *meso*-diaminopimelic acid, arabinose, and galactose. Mycolic acids are not produced. The major menaquinones are MK-10 and MK-11. Straight-chain saturated fatty acids are mainly palmitic and stearic acids; oleic acid is the predominant unsaturated fatty acid. Tuberculostearic acid is produced.

Source: middle-ear effusions of patients with otitis media.

DNA G+C content (mol%): 65–72 (T_m).

Type strain: 234/92, ATCC 51513, CCUG 32254, CIP 104075, DSM 8821, JCM12146, LMG 19071.

Sequence accession no. (16S rRNA gene): X73976.

Family II. **Dietziaceae** Rainey, Ward-Rainey and Stackebrandt 1997, 486[VP] emend. Zhi, Li and Stackebrandt 2009, 595[VP]

Fred A. Rainey

Diet.zi.a.ce′a.e. N.L. fem. n. *Dietzia* type genus of the family; suff. *-aceae* ending to denote a family. N.L. fem. pl. n. *Dietziaceae* the *Dietzia* family.

Aerobic, **Gram-stain-positive**, cocci/short rods, **chemo-organotrophs**. **Peptidoglycan of the A1γ type** containing ***meso*-diaminopimelic acid**. Short-chain **mycolic acids**. **MK-8(H_2)** is the predominant menaquinone. Member of the order *Corynebacteriales*, of the class *Actinobacteria* based on 16S rRNA gene based phylogeny. The pattern of 16S rRNA signatures defining the family consists of nucleotides at positions 241:285 (U–G), 250 (U), 316:337 (C–G), 418:425 (U–A), 599:639 (C–G), 662:743 (C–G), 987:1218 (A–U), 1000:1040 (A–U), 1059:1198 (U–A), and 1115:1185 (C–G). The family contains the type genus *Dietzia* Rainey et al. (1995b).

DNA G+C content (mol%): 65.5–73.

Type genus: **Dietzia** Rainey, Klatte, Kroppenstedt and Stackebrandt 1995b, 33[VP].

Genus I. **Dietzia** Rainey, Klatte, Kroppenstedt and Stackebrandt 1995b, 33[VP] emend. Kämpfer, Langer, Martin, Jäckel and Busse 2010, 394[VP]

Fred A. Rainey

Diet′zi.a. N.L. fem. n. *Dietzia* honoring Alma Dietz, an American microbiologist.

Gram-stain-positive, non-spore-forming cocci that germinate into short rods. Rod-shaped cells exhibit a morphogenetic cycle. **Aerobic** and **chemo-organotrophic**. **Mesophilic**. **Catalase-positive**. The diagnostic amino acid of the peptidoglycan is ***meso*-diaminopimelic acid**; the glycan moiety of cell wall contains *N*-acetyl residues (*N*-acetylmuramic acid). The major cell-wall sugars are arabinose and galactose. **Short-chain mycolic acids** with 33–39 carbon atoms are present. The long-chain cellular fatty acids are predominantly straight-chain saturated and monounsaturated fatty acids. **Tuberculostearic acid** is present. The polar lipids can include phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and phosphatidylinnositol mannosides. **All species studied contain phosphatidylglycerol**. **Menaquinone MK-8 (H_2)** is the major menaquinone. Species of the genus have been isolated from air, soil, lake sediments, deep-sea mud, deep-sea sediments, plant tissues, skin, and intestines of carp, fish-egg processing plant water, human perianal swab, human bone biopsy, and human skin.

Based on 16S rRNA gene sequence phylogeny the species of the genus form a distinct family level lineage within the order *Corynebacteriales* of the class *Actinobacteria*.

DNA G+C content (mol%): 65.5–73.

Type species: **Dietzia maris** (Nesterenko, Nogina, Kasumova, Kvasnikow and Batrako 1982) Rainey, Klatte, Kroppenstedt and Stackebrandt 1995b, 33[VP].

Further descriptive information

Phylogeny. 16S rRNA gene sequence phylogenetic analyses of the species of the genus *Rhodococcus* have led to the formation of the genus *Dietzia* as a home for the misclassified *Rhodococcus* species, *Rhodococcus maris* (Rainey et al., 1995a, 1995b). In the 16S rRNA gene sequence analysis of the sequences of the type strains of type species of all actinomycete genera, the species *Dietzia maris* was found to represent a distinct lineage within the radiation of mycolic acid-containing bacteria at the family level, and the family *Dietziaceae* was described (Stackebrandt et al., 1997). This single-genus family was described solely on the basis of phylogenetic position and the following set of defined 16S rRNA gene nucleotide signatures (Stackebrandt et al., 1997): 70–98 (U–A), 293:304 (G–U), 307 (U), 418:425 (U–A), 508 (U), 614:626 (U–G), 631 (G), 661:744 (A–U), 771:808 (A–U), 824:876 (C–G), 825:875 (G–C), 843 (C), 1049:1198 (U–A), and 1122:1151 (A–U). Li et al. (2009) emended the description of the family *Dietziaceae* by providing a new set of nucleotide signatures as follows: 241:285 (U–G), 250 (U), 316:337 (C–G), 418:425 (U–A), 599:639 (C–G), 662:743 (C–G), 987:1218 (A–U), 1000:1040 (A–U), 1059:1198 (U–A) and 1115:1185 (C–G). Notably, with the addition of new species to the genus *Dietzia* as well as the addition of new genera to and species to the order *Corynebacteriales*, all but one of the original nucleotide signatures in the set defining the family no longer hold true. With the exception of the signature 418:425 (U–A), all of the nucleotide signatures included in the emended family are new (Li et al., 2009).

16S rRNA gene sequence-based phylogenetic analyses show the species of the genus *Dietzia* to form a monophyletic branch within the radiation of the genera of the order *Corynebacteriales* (Figure 84). The type strains of the 11 species of the genus *Dietzia* share 16S rRNA gene sequence pairwise similarities in the range 95.5–99.4% which in turn is reflected in the pattern of clustering displayed in Figure 85. Eight of the 11 species fall into three clusters that are supported by bootstrap values of at least 99%. Cluster *A* contains the species *Dietzia cercidiphylli*, *Dietzia natronolimnaea*, and *Dietzia psychralcaliphila* which share 99.1–99.3% pairwise sequence similarity (Figure 85). Another three species, *Dietzia kunjamensis*, *Dietzia maris*, and *Dietzia schimae*, comprise a cluster designated *B* (Figure 85) and share 99.8–99.1% pairwise sequence similarity. Cluster *C* is a two species cluster with *Dietzia cinnamea* and *Dietzia papillomatosis* (Figure 85) sharing 98.5% pairwise sequence similarity. The species *Dietzia aerolata* falls between the species of clusters *A* and *B* and its position is supported by an 80% bootstrap value (Figure 85). The position of *Dietzia lutea* between the *A*/*B* cluster and cluster *C* is supported by an 88% bootstrap value. The deepest branching species of the *Dietzia* lineage is *Dietzia timorensis* which shares 95.5–98.5% pairwise sequence similarity with other *Dietzia* species (Figure 85). It should be noted that in the case of a number of highly similar 16S rRNA gene sequences, extended branching is observed (Figure 84 and Figure 85). These extended branches are due to sequence quality with very small differences between the sequences

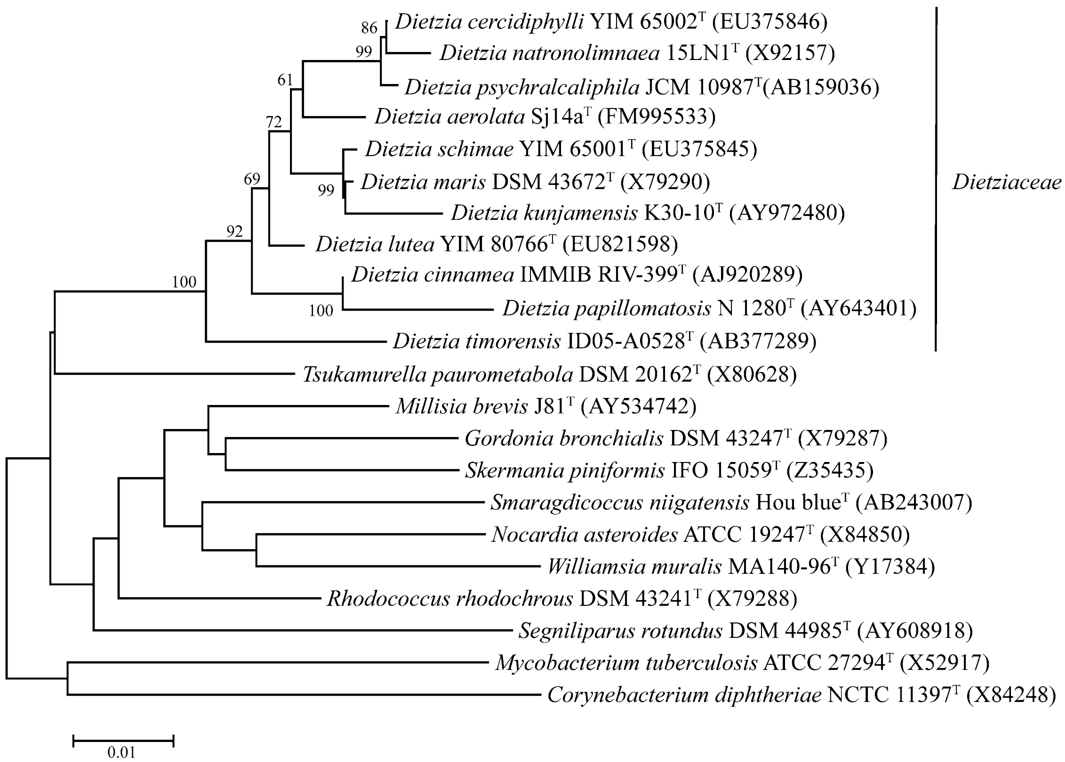

FIGURE 84. 16S rRNA gene sequence based phylogeny showing the position of the species of the genus *Dietzia* within the radiation of the type species of the genera of the order *Corynebacteriales*. The scale bar infers one nucleotide substitution per 100 nucleotides. The phylogeny was reconstructed from distance matrices using the neighbor-joining method.

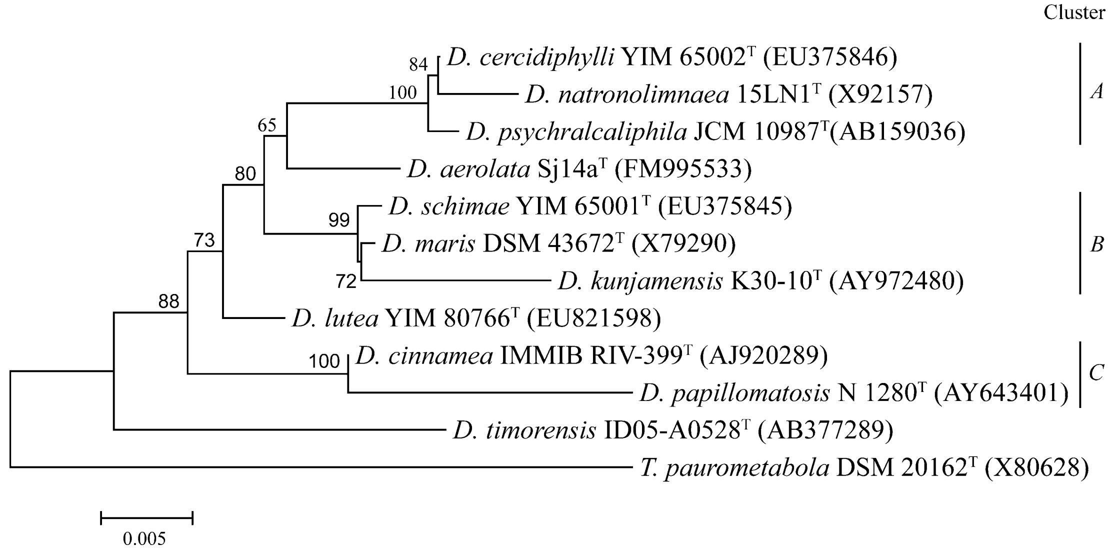

FIGURE 85. 16S rRNA gene sequence based phylogeny showing the relationships of the species of the genus *Dietzia*. The scale bar infers 0.5 nucleotide substitution per 100 nucleotides. The phylogeny was reconstructed from distance matrices using the neighbor-joining method. The outgroup species used in the analyses was *Tsukamurella paurometabola*.

being compared. It is recommended that new 16S rRNA gene sequences be obtained for the type strains of species described before high quality sequencing became routine.

The high 16S rRNA gene sequence similarity values obtained between a number of species have required DNA–DNA hybridization studies to determine the species status of a number of new isolates. The majority of the DNA–DNA hybridization values reported in the literature are in the 40–50% range. There is little correlation between the higher 16S rRNA gene sequence similarities and the respective DNA–DNA hybridization values.

For the genus *Dietzia* there is only one report of a DNA–DNA hybridization study between two strains of the same species (i.e. strains 14LN1 and 15LN1^T of the species *Dietzia natronolimnaea*) which had a value of 83% (Duckworth et al., 1998).

Chemotaxonomic properties. The cell-wall structure has been determined for the type strains of all described species of the genus *Dietzia*, with the exception of *Dietzia aerolata* (Kämpfer et al., 2010). The cell-wall chemotype of the species of the genus *Dietzia* is type IV (Lechevalier and Lechevalier, 1970). The diagnostic amino acid of the peptidoglycan is *meso*-diaminopimelic acid and the peptidoglycan is of the A1γ type (Schleifer and Kandler, 1972). The cell-wall sugars are arabinose and galactose. The major isoprenologue detected in species of the genus *Dietzia* is the dihydrogenated menaquinone with eight isoprene units, i.e. MK-8(H_2). The presence of the isoprenologue MK-7(H_2) as a minor menaquinone component has been reported for the species *Dietzia cinnamea* (Yassin et al., 2006) and *Dietzia papillomatosis* (Jones et al., 2008). In the case of *Dietzia aerolata*, Kampfer et al. (2010) reported the detection of MK-8(H_2), MK-7(H_2) (14%), MK-9(H_2) (2%), MK-7 (<1%), and MK-8 (<1%).

The whole-cell fatty acids of the species of the genus *Dietzia* consist of predominantly straight-chain saturated and unsaturated fatty acids. The following fatty acids have been detected in all described species: $C_{14:0}$; $C_{16:1}$ ω6*c* and $C_{16:1}$ ω7*c*; $C_{16:0}$; 10-methyl $C_{17:0}$, and 10-methyl $C_{18:0}$. The small differences that exist between fatty acid profiles to date have not been used for the differentiation of *Dietzia*. This is partly due to the fact that the majority of species of the genus are represented by a single strain, the type strain, and so nothing is known about intraspecies fatty acid profile variation. For the species of the genus *Dietzia*, various combinations of the polar lipids (phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol) and phosphatidylinositol mannosides are found. Phosphatidylglycerol is the only polar lipid present in all strains analyzed. Five different polar lipid profiles have been detected for the ten species of the genus for which polar lipid profiles have been determined. No polar lipid profile has been determined for the species *Dietzia psychralcaliphila* (Yumoto et al., 2002). A profile consisting of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol is found for *Dietzia maris* (Rainey et al., 1995b), *Dietzia cinnamea* (Yassin et al., 2006), *Dietzia papillomatosis* (Jones et al., 2008), and *Dietzia natronolimnaea* (Duckworth et al., 1998). The species *Dietzia aerolata* (Kämpfer et al., 2010) and *Dietzia cercidiphylli* (Li et al., 2008) have the polar lipids (phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol) and phosphatidylinositol mannosides. A polar lipid profile containing phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol is found for *Dietzia kunjamensis* (Mayilraj et al., 2006) and *Dietzia schimae* (Li et al., 2008). A combination of all of the polar lipids (phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol) and phosphatidylinositol mannosides known for the genus is found in *Dietzia lutea* (Li et al., 2009). The most recently described species *Dietzia timorensis* (Yamamura et al., 2010) has a unique polar lipid profile containing phosphatidylglycerol and phosphatidylinositol.

Ecology and habitats. Strains of the genus *Dietzia* have been isolated from a wide variety of habitats including animal and human sources. Most species are represented by a single strain, the type strain, and would seem to have been isolated as part of overall diversity studies rather than targeted or specific enrichment approaches. *Dietzia maris* has been isolated from halibut (Harrison, 1929), soils, and the skin and intestinal contents of carp (*Cyprinus carpio*) (Nesterenko et al., 1982). There are reports in the literature of the isolation of *Dietzia maris* strains from deep-sea muds (Takami et al., 1997), deep-sea trenches in the Pacific Ocean (Colquhoun et al., 1998), the dinoflagellate *Pyrodinium bahamense* (Azanza et al., 2006), and from clinical samples (Pidoux et al., 2001; Reyes et al., 2006). *Dietzia aerolata* was isolated from a bioaerosol collected in a duck barn in Germany (Kämpfer et al., 2010). The species *Dietzia cercidiphylli* and *Dietzia schimae* were isolated from surface sterilized plant material of *Schima* sp. and *Cercidiphyllum japonicum* using tap water yeast extract agar (Li et al., 2008). *Dietzia cinnamea* (Yassin et al., 2006) and *Dietzia papillomatosis* (Jones et al., 2008) are species of human origin. Soil was the source of the species *Dietzia lutea* (Li et al., 2009), *Dietzia kunjamensis* (Mayilraj et al., 2006), and *Dietzia timorensis* (Yamamura et al., 2010) while an additional environmental isolate *Dietzia natronolimnaea* (Duckworth et al., 1998) was recovered from littoral sediments of a soda lake in Kenya. In the search for organisms capable of degradation of petroleum products at low temperatures, the species *Dietzia psychralcaliphila* was isolated from water from a drain pool in a fish egg processing plant (Yumoto et al., 2002). A search of the public databases demonstrates that large numbers of 16S rRNA gene sequences recovered from various habitats have been shown to fall within the radiation of the species of the genus *Dietzia*. Koerner et al. (2009) speculated on the role of species of the genus *Dietzia* as emerging opportunistic pathogens.

Nutrition and growth conditions

The species of the genus *Dietzia* are chemo-organotrophs with optimal temperatures for growth in the mesophilic range and pH optima in the neutral/alkaline range. The species *Dietzia psychralcaliphila* has been described as a psychrophilic, alkaliphile capable of growing at 5°C and optimally at pH values of 9–10 (Yumoto et al., 2002). *Dietzia natronolimnaea* is also an alkaliphile having an optimum pH for growth of 9.0 (Duckworth et al., 1998). Of those tested for growth at high NaCl concentrations the species *Dietzia maris* (Rainey et al., 1995b), *Dietzia lutea* (Li et al., 2009), and *Dietzia schimae* (Li et al., 2008) have been shown to grow at a NaCl concentration of 15% (w/v).

The substrates reported in the literature to be used as sole carbon sources are given in Table 34. The data presented in Table 34 are from all papers describing new species of the genus *Dietzia* and not just the paper describing the species in question. As additional species have been added to the genus, comparative studies have been made and new data on existing species have been accumulated. For some species, namely *Dietzia kunjamensis* (Mayilraj et al., 2006) and *Dietzia psychralcaliphila* (Yumoto et al., 2002), there are many discrepancies between the substrate utilization data presented in the original publication and that presented in subsequent publications even though the same type strains have been used as reference material in comparative studies. The substrates for which conflicting data exist are recorded as +/− in Table 34. The high number of nd (not determined) entries in Table 34 indicate that no formal standards for the description of species of the genus *Dietzia* have been proposed and so it continues to be difficult to carry out comparative studies and differentiate species on the basis of phenotype.

The information provided in the species descriptions below is a compilation of data from the original publication of the particular species and subsequent publications in which data for the type strains of other previously described species were determined for comparative purposes.

[b]On TSA.

List of species of the genus *Dietzia*

1. **Dietzia maris** Rainey, Klatte, Kroppenstedt and Stackebrandt 1995b, 33[VP] (*Rhodococcus maris* Nesterenko, Nogina, Kasumova, Kvasnikow and Batrako 1982, 11)

ma′ris. L. gen. n. *maris* of the sea.

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, non-acid-fast, V-forms and coccoid to rod–shaped cells, which exhibit snapping division. Circular, raised, butyrous, glistening, orange pigmented colonies with entire margins on nutrient agar (NA) plates. Catalase-positive. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{14:0}$ (0.8%), $C_{15:1}$ ω8*c* (0.15%), $C_{15:1}$ ω5*c* (0.42%), $C_{16:1}$ ω6*c* and $C_{16:1}$ ω7*c* (10.6%), 10-methyl $C_{16:0}$ (0.6%), $C_{16:0}$ (15.3%), $C_{17:1}$ ω8*c* (17.2%), $C_{10:0}$ (13.3%), 10-methyl $C_{17:0}$ (5.3%), $C_{18:1}$ ω9*c* (13.9%), $C_{18:0}$ (12.3%), and 10-methyl $C_{18:0}$ (10.3%). Mycolic acids containing 33–38 carbon atoms are present. The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. MK-8(H_2) is the major menaquinone. Growth occurs between 10 and 45°C, with optimal growth occurring at 28°C. Growth occurs in the presence of 15% (w/v) NaCl. Nitrate is reduced. Methyl red is negative. H_2S and indole are not produced. Negative for milk coagulation. Degrades gelatin, Tweens 20, 40, 60, and 80, but not casein, cellulose, guanine, hypoxanthine, L-tyrosine, or xanthine. Urea is hydrolyzed. Acetate, amygdalin, butyrate, citrate (some strains), D-fructose, D-glucose, glycerol (variable results), malate, D-maltose (variable results), D-mannose (some strains), D-melezitose, methyl-α-D-mannopyranoside, potassium 5-ketogluconate, pyruvate, sucrose (some strains), succinate, and D-xylose (weak and variable) are used as sole carbon sources. The following substrates are not used as sole carbon sources: D-adonitol, esculin, D-arabinose, L-arabinose, D-arabitol, arbutin, D-cellobiose, dulcitol, L-fucose, D-galactose, gentiobiose, glycogen, inositol, inulin, D-lactose, D-lyxose, D-mannitol, D-melibiose, methyl-α-D-glucopyranoside, methyl-β-D-xylopyranoside, *N*-acetylglucosamine, D-raffinose, L-rhamnose, D-ribose, salicin, sorbitol, L-sorbose, D-tagatose, D-trehalose, D-turanose, xylitol, and L-xylose.

Source: soil; skin, and intestinal tracts of carp (*Cyprinus carpio*).

DNA G+C content (mol%): 70.4 (HPLC).

Type strain: ATCC 35013, AUCNM A-593, CCUG 44488, CIP 104188, DSM 43672, IEGM 55, IFO (now NBRC) 15801, IMV 195, JCM 6166, LMG 5361, NRRL B-16941, VKM Ac-593.

Sequence accession no. (16S rRNA gene): X79290.

2. **Dietzia aerolata** Kämpfer, Langer, Martin, Jackel and Busse 2010, 395[VP]

a.e.ro.la′ta. Gr. n. *aer* air; L. fem. part. adj. *lata* carried; N.L. fem. part. adj. *aerolata* airborne.

Aerobic, Gram-stain-positive staining, nonmotile, coccoid shaped cells. Deep orange pigmented colonies on TSA plates. Catalase- and oxidase-positive. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely: $C_{14:0}$ (0.5%), $C_{16:1}$ ω6*c* and $C_{16:1}$ ω7*c* (5.6%), $C_{16:0}$ (22.7%), $C_{17:1}$ ω8*c* (5.0%), $C_{17:0}$ (14.0%), 10-methyl $C_{17:0}$ (0.7%), $C_{18:1}$ ω9*c* (19.7%), $C_{18:0}$ (6.9%), 10-methyl $C_{18:0}$ (13.2%), $C_{19:0}$ (8.4%), $C_{20:4}$ ω6,9,12,15*c* (1.4%), and $C_{20:0}$ (0.4%). The polar lipid profile consists of phosphatidylglycerol, diphosphatidylglycerol, phophatidylinositol, phosphatidylinositol mannoside, two unknown glycolipids, and three unknown polar lipids. Mycolic acids are present. The major polyamines are spermine and spermidine. MK-8(H_2) is the major menaquinone. Growth occurs between 10 and 30°C, with optimal growth occurring at 25–30°C. D-Glucose and D-mannose are utilized as sole carbon sources. D-Adonitol, L-arabinose, D-arabitol, arbutin, cellobiose, inositol, inulin, maltose, melibiose, *N*-acetylglucosamine, raffinose, L-rhamnose, salicin, sucrose, trehalose, and D-xylose are not utilized.

Source: air of a duck barn.

DNA G+C content (mol%): not determined.

Type strain: strain Sj14a, CCM 7659, DSM 45334.

Sequence accession no. (16S rRNA gene): FM995533.

3. **Dietzia cercidiphylli** Li, Zhao, Zhang, Klenk, Pukall, Qin, Xu and Li 2008, 2552[VP]

cer.ci.di.phyl′li. N.L. gen. n. *cercidiphylli* of the plant *Cercidiphyllum*, isolated from root sample of *Cercidiphyllum japonicum.*

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, non-acid–alcohol-fast, short rods (which exhibit snapping division), and V-forms. Circular, smooth, opaque reddish orange pigmented colonies on trypticase soy agar (TSA) plates. Catalase-positive; oxidase-negative. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{14:0}$ (1.1%), $C_{15:1}$ iso (0.4%), $C_{16:0}$ iso (1.6%), $C_{16:1}$ ω9*c* (0.5%), $C_{16:1}$ ω6*c* and $C_{16:1}$ ω7*c* (18.7%), 10-methyl $C_{16:0}$ (1.1%), $C_{16:0}$ (18.9%), $C_{17:1}$ anteiso ω9*c* (0.9%), $C_{17:1}$ ω8*c* (3.7%), $C_{17:1}$ ω7*c* (2.2%), $C_{17:0}$ iso (0.2%), $C_{17:0}$ anteiso (0.9%), 10-methyl $C_{17:0}$ (0.4%), $C_{18:1}$ ω7*c* (3.4%), $C_{18:1}$ ω9*c* (27.9%), and 10-methyl $C_{18:0}$ (18.0%). Mycolic acids containing 33–40 carbon atoms are present. The polar lipid profile consists of phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside. MK-8(H_2) is the major menaquinone. Growth occurs between 10 and 37°C, with optimal growth occurring at 28°C. Growth occurs between pH 6 and 9, with optimal growth at pH 7. Growth occurs in the presence of 10% (w/v) NaCl. Nitrate is not reduced. Voges–Proskauer and methyl red tests are negative. H_2S and indole are not produced. Negative for milk coagulation and peptonization. Gelatin and starch are not hydrolyzed. Urea, Tweens 20, 40, and 80 are hydrolyzed. L-Arabinose, arbutin, D-fructose, D-glucose, D-lactose, D-lyxose, maltose, D-mannose, potassium 5-ketogluconate, sucrose (weakly), D-tagatose, and turanose are used as sole carbon sources. The following substrates are not used as sole carbon sources: D-adonitol, esculin, amygdalin, D-arabinose, L-arabitol, D-arabitol, cellobiose, dulcitol, L-fucose, D-fucose, gentiobiose, glycerol, glycogen, inositol, inulin, D-mannitol, melezitose, melibiose, methyl-α-D-glucopyranoside, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, *N*-acetylglucosamine, potassium gluconate, potassium 2-ketogluconate, raffinose, L-rhamnose, D-ribose, salicin, D-sorbitol, starch, trehalose, xylitol, L-xylose, and D-xylose.

Source: surface sterilized root sample of *Cercidiphyllum japonicum* collected from Yunnan Province, southwest China.

DNA G+C content (mol%): 72.6 (HPLC).

Type strain: YIM 65002, CCTCC AA 207016, DSM 45140, JCM 16002.

Sequence accession no. (16S rRNA gene): EU375846.

4. **Dietzia cinnamea** Yassin, Hupfer and Schaal 2006, 644[VP]

cin.na′me.a. L. fem. adj. *cinnamea* of or from cinnamon referring to the color of the cellular biomass.

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, non-acid-fast, V-forms and rod–shaped cells, which exhibit snapping division. Circular, convex, shiny, yellow-pigmented colonies on Columbia agar supplemented with 5% sheep blood, and orange-pigmented colonies on modified Bennett's agar after growth for 5d at 30°C. Catalase-positive; oxidase-negative. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. The glycan moiety of the cell wall contains N-acetyl residues (*N*-acetylmuramic acid). Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{14:0}$ (0.65%), $C_{15:1}$ *cis*-10 (0.5%), $C_{15:0}$ (4.66%), $C_{16:1}$ *cis*-9 (2.35%), $C_{16:1}$ *cis*-10 (12.2%), $C_{16:0}$ (22.97%), 10-methyl $C_{16:0}$ (0.56%), $C_{17:0}$ *cis*-9 (11.43%), $C_{17:0}$ (4.0%), 10-methyl $C_{17:0}$ (5.23%), $C_{18:0}$ *cis*-9 (13.49%), $C_{18:0}$ (0.32%), 10-methyl $C_{18:0}$ (20.65%), and $C_{19:1}$ *cis*-9 (1.1%). The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. Pyrolysis of mycolic acids releases the following fatty acids: $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, $C_{17:0}$, $C_{18:1}$, and $C_{18:0}$. MK-8(H_2) is the major menaquinone and MK-7(H_2) is the minor one. Growth occurs between 22 and 45°C. No growth at 5°C. Growth occurs pH 7 and 10 but not at pH 5. Growth occurs in the presence of 12% (w/v) NaCl. Nitrate is reduced. Degrades cellulose, testosterone, and urea but not adenine, casein, elastin, esculin, gelatin, guanine, hypoxanthine, tyrosine, or xanthine. Acetate, D-fructose, D-glucose, D-maltose, 1,2-propanediol, salicin, and D-tagatose are used as sole carbon sources. The following substrates were not used as sole carbon sources: adipate, D-adonitol, isoamyl alcohol, L-arabinose, 2, 3-butanediol, D-cellobiose, citrate, *meso*-erythritol, D-galactose, gluconate, gentiobiose, *m*-hydroxybenzoate, *p*-hydroxybenzoate, inositol, lactate, D-lactose, L-lyxose, D-mannitol, melezitose, D-raffinose, L-rhamnose, sorbitol, sucrose, D-trehalose, and D-xylose. Unable to use acetamide, L-alanine, arginine, gelatin, ornithine, proline, or serine as simultaneous carbon and nitrogen sources. The utilization of the following carbon sources is reported to be both positive and negative in different studies: adonitol, L-arabinose, butane-2, 3-diol, D-cellobiose, *meso*-erythritol, D-galactose, *myo*-inositol, D-lactose, D-mannitol, D-melezitose, D-raffinose, sucrose, trehalose, and D-xylose.

Source: perianal swab of a patient with a bone marrow transplant.

DNA G+C content (mol%): 72.3 (HPLC).

Type strain: IMMIB RIV-399, CCUG 50875, DSM 44904, JCM 13663, NBRC 102147.

Sequence accession no. (16S rRNA gene): AJ920289.

5. **Dietzia kunjamensis** Mayilraj, Suresh, Kroppenstedt and Saini 2006, 1670[VP]

kun.ja.men′sis. N.L. fem. adj. *kunjamensis* pertaining to Kunjam Pass of the cold desert of the Indian Himalayas.

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, rod–coccus shaped cells, occurring in groups. Colonies are small, smooth, glistening, convex, and coral red-pigmented on TSA. Catalase- and oxidase-positive. Negative for H_2S production, indole, methyl red, and Voges–Proskauer tests. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. The glycan moiety of the cell wall contains N-acetyl residues (*N*-acetylmuramic acid). Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{16:0}$ (14.43%), $C_{16:1}$ *cis*-10 (6.0%), $C_{17:0}$ (12.95%), $C_{17:1}$ *cis*-9 (8.85%), $C_{17:1}$ *cis*-10 (7.41), $C_{18:1}$ *cis*-9 (30.39%), and tuberculostearic acid (10.51%). Mycolic acids containing 33–40 carbon atoms are present. The polar lipid profile consists of phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol. MK-8(H_2) is the major menaquinone. Nitrate is reduced. Degrades cellulose, Tweens 40 and 60, but not casein, DNA, and starch. Acetic acid, L-arabinose, L-asparagine, dextrin, D-fructose, D-fructose 6-phosphate, L-fucose, gentiobiose, D-glucose, L-glutamic acid, glycerol, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketovaleric acid, maltotriose, D-mannose, palatinose, D-psicose, D-ribose, succinic acid monomethyl ester, thymidine, D-trehalose, turanose, D-xylose, propionic acid, and pyruvic acid are used as sole carbon sources. Adenosine, 2′-deoxyadenosine, L-alaninamide, D- and L-alanine, AMP, 2, 3-butanediol, α-cyclodextrin, β-cyclodextrin, *N*-acetyl-D-glucosamine, *N*-acetyl-β-D-mannosamine, amygdalin, D-arabitol, arbutin, citrate, D-cellobiose, D-galactose, D-galacturonic acid, D-gluconic acid, α-D-glucose 1-phosphate, D-glucose 6-phosphate, methyl-α-D-glucoside, *N*-acetyl-L-glutamic acid, DL-α-glycerol phosphate, glycyl L-glutamic acid, L-alanyl glycine, glycogen, α-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, inosine, *myo*-inositol, inulin, α-ketoglutaric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, α-D-lactose, lactulose, D- and L-malic acid, maltose, mannan, D-mannitol, D-melezitose, D-melibiose, methyl-α-D-galactoside, methyl-β-D-galactoside, methyl-D-glucose, methyl-β-D-glucoside, methyl-α-D-mannoside, putrescine, L-pyroglutamic acid, pyruvic acid methyl ester, D-raffinose, L-rhamnose, salicin, sedoheptulosan, serine, D-sorbitol, stachyose, succinic acid, succinamic acid, sucrose, D-tagatose, TMP, UMP, uridine, and xylitol are not utilized. Acid is produced from mannitol and sucrose but not from arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, raffinose, rhamnose, salicin, sorbitol, or xylose. Growth occurs between 20 and 37°C with optimal growth at 25°C. Growth does not occur at 5, 10, or 45°C. Growth occurs between pH 7 and 10 with optimal growth at pH 8. Growth does not occur at pH 5. Weak growth occurs in the presence of 7% (w/v) NaCl.

Source: soil 45 cm below an ice glacier, at 4200 m above sea level, Kunjam Pass, Himachal Pradesh, India.

DNA G+C content (mol%): 67 (HPLC).

Type strain: K30-10, DSM 44907, JCM 13325, MTCC 7007.

Sequence accession no. (16S rRNA gene): AY972480.

6. **Dietzia lutea** Li, Chen, Zhao, Klenk, Pukall, Zhang, Tang and Li 2011, 1[VP] (Effective publication: Li, Chen, Zhao, Klenk, Pukall, Zhang, Tang and Li 2009, 122.)

lu′te.a. L. fem. adj. *lutea* orange-yellow colored.

Aerobic, Gram-stain-positive, nonmotile, non-spore-forming, non-acid-fast, V-forms and short rod–coccus shaped cells, which exhibit snapping division. Circular, convex, smooth, opaque, orange-yellow colonies on TSA plates. Catalase-positive; oxidase-negative. The cell wall amino acid

is *meso*-diaminopimelic acid and the major cell sugars are arabinose and galactose. The major whole-cell fatty acids are $C_{14:0}$ (1.03%), $C_{15:0}$ (3.71%), $C_{16:0}$ (15.42%), $C_{16:1}$ *cis*-9 (3.86%), $C_{17:0}$ (22.42%), $C_{17:1}$ *cis*-9 (12.29%), 10-methyl $C_{17:0}$ (2.95%), $C_{18:0}$ (8.09%), $C_{18:1}$ *cis*-9 (10.24%), 10-methyl $C_{18:0}$ (tuberculostearic acid) (7.86%), $C_{19:0}$ (2.56%), $C_{16:1}$ *trans* 9/15i2-OH (6.70%), and $C_{18:1}$ *trans* 9/t6/c11 (1.77%). Mycolic acids are present. The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside. MK-8(H_2) is the major menaquinone. Growth occurs between 10 and 45°C, with optimal growth at 28°C. Growth occurs between pH 5 and 9, with optimal growth at pH 7. Growth occurs in the presence of 15% (w/v) NaCl. Nitrate is not reduced. Voges–Proskauer and methyl red tests are negative. H_2S and indole are not produced. Negative for milk coagulation and peptonization. Cellulose, gelatin, starch, and urea are not hydrolyzed. Tweens 20, 40, and 80 are hydrolyzed. Alkaline phosphatase, α-galactosidase, β-glucuronidase and α-glucosidase enzymic activities are detected. *N*-acetyl-β-glucosaminidase, α-mannosidase, β-fucosidase, trypsin, α-chymotrypsin, β-galactosidase, and β-glucosidase are present, but not esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, cysteine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase when using the API ZYM test strips. Utilizes L-arabinose, D-arabinose, esculin, D-fructose, D-galactose, D-glucose, glycerol, inositol, D-lyxose, D-mannitol, D-mannose, methyl-α-D-manno-pyranoside, methyl-β-D-xylopyranoside, L-rhamnose, D-ribose, L-sorbose, D-xylose, and L-xylose. D-Adonitol, starch, amygdalin, L-arabitol, D-arabitol, arbutin, D-cellobiose, dulcitol, erythritol, L-fucose, gentiobiose, glycogen, inulin, D-lactose, D-maltose, D-melezitose, D-melibiose, methyl-α-D-glucopyranoside, *N*-acetylglucosamine, potassium gluconate, potassium 2-keto-gluconate, potassium 5-keto-gluconate, D-raffinose, salicin, D-sorbitol, sucrose, D-tagatose, D-trehalose, D-turanose, or xylitol are not utilized as sole carbon sources.

Source: desert soil in Egypt.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: YIM 80766, KCTC 19232, DSM 45074, CCTCC AA 207008.

Sequence accession no. (16S rRNA gene): EU821598.

7. **Dietzia natronolimnaea** Duckworth, Grant, Grant, Jones, Meijer 1999, 1[VP] (Effective publication: Duckworth, Grant, Grant, Jones, Meijer 1998, 365.)

na.tro.no.lim.na′e. a. N.L. n. *natron* (arbitrarily derived from the Arabic n. natrun or natron), soda, sodium carbonate; N.L. fem. adj. *limnaea* (from Gr. fem. adj. limnaia) of or from the marsh; N.L. fem. adj. *natronolimnaea*, of or from a soda lake (marsh).

Aerobic, Gram-stain-positive, nonmotile, non-spore-forming, non-acid-fast, V-forms and short rod-shaped cells, which exhibit snapping division. Circular, convex, glistening soft pink to coral red colonies. Catalase-positive; oxidase-negative. The cell wall amino acid is *meso*-diaminopimelic acid and the major cell sugars are arabinose and galactose. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{14:0}$ (0.66%), $C_{15:0}$ (0.79%), $C_{16:1}$ *cis*-9 (5.37%), $C_{16:1}$ *cis*-10 (8.29%), $C_{16:0}$ (28.50%), $C_{17:0}$ *cis*-9 (3.49%), $C_{17:0}$ (2.1%), $C_{18:0}$ *cis*-9 (31.1%), $C_{18:0}$ (0.75%), 10-methyl $C_{18:0}$ (18.26%), and $C_{19:1}$ *cis*-9 (0.73%). Mycolic acids containing 34–38 carbon atoms are present. The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. MK-8(H_2) is the major menaquinone. Growth occurs between 20 and 40°C, with optimal growth at 30°C. Growth occurs between pH 6 and 10, with optimal growth at pH 9. Growth occurs in the presence of 10% (w/v) NaCl. Nitrate reduction has been reported as both positive and negative. Indole is produced. Cellulose, starch, and urea are hydrolyzed. Gelatin is not hydrolyzed. Alkaline phosphatase, esterase (C4), esterase/lipase (C8), leucine arylamidase, cysteine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase enzymic activities are detected. Lipase (C14), valine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and β-fucosidase were not detected using the API ZYM test strips. Utilizes L-arginine, L-asparagine, glycine, L-methionine, L-phenylalanine, L-proline, L-serine, starch, succinate, and L-valine under alkaline conditions, but not L-alanine, formate, fumarate, D-galactose, D-lactose, L-lysine, pyruvate, or D-xylose. Under neutral conditions acetate, *N*-acetylglucosamine, citrate, D-fructose, fumarate, D-glucose, glutamate, glycogen, 3-hydroxybutyrate, mannitol, L-proline, propionate, succinate, suberate, L-serine, and valerate are utilized but not L-alanine, L-arabinose, caprate, L-fucose, D-galactose, histidine, 4-hydroxybenzoate, inositol, itaconate, 2-ketogluconate, 3-hydroxybenzoate, 5-ketogluconate, DL-lactate, lactose, malonate, maltose, D-melibiose, rhamnose, D-ribose, salicin, D-sorbitol, or sucrose.

Source: littoral sediments of Lake Oloidien (Little Lake Naivasha), Kenya.

DNA G+C content (mol%): 66.1 (T_m).

Type strain: 15LN1, CBS 107. 95, DSM 44860, JCM 11417.

Sequence accession no. (16S rRNA gene): X92157.

8. **Dietzia papillomatosis** Jones, Koerner, Natarajan, Perry and Goodfellow 2008, 71[VP]

pa.pil.lo.ma.to′sis. N.L. gen. n. *papillomatosis* of papillomatosis.

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, non-acid–alcohol-fast, V-forms with a rod–coccus life cycle, and reproduction by snapping division. Resistant to lysozyme. Circular, convex, shiny, orange-pigmented colonies on modified Bennett's agar after growth for 5 days at 30°C. Neither aerial hyphae nor diffusible pigments are formed. Catalase-positive; oxidase-negative. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. The glycan moiety of the cell wall contains N-acetyl residues (*N*-acetylmuramic acid). Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely pentadecanoic acid ($C_{15:0}$; 5.4%), hexadecanoic acid ($C_{16:0}$; 21.1%), monounsaturated hexadecenoic acid ($C_{16:1}$; 3.0%), septadecanoic acid ($C_{17:0}$; 6.1%), monounsaturated septadecenoic acid ($C_{17:1}$; 2.7%), monounsaturated octadecenoic acid ($C_{18:1}$; 9.0%), tuberculostearic acid 10-methyl $C_{18:0}$ (22.1 %), nonadecanoic acid ($C_{19:0}$; 2.6%), and unidentified peaks with the retention times of 19.99 (10.6%), 21.61 (5.6%), and 21.88 (5.7%). The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. MK-8(H_2) is the major menaquinone and MK-7(H_2) is the minor one. Nitrate is reduced to nitrite, but nitrite is not reduced. Degrades cellulose, chitin, starch, L-tyrosine, Tweens 20, 40, 60, and 80, but

not adenine, casein, DNA, elastin, gelatin, hypoxanthine, pectin, RNA, tributyrin, uric acid, xanthine, or xylan. Allantoin, arbutin, and urea are hydrolyzed but not esculin. Adonitol, isoamyl alcohol, L-arabinose, arbutin, *m*-hydroxybenzoic acid, butane-1,3-diol, butane-1, DL-β-hydroxybutyric acid, 4-diol, butane-1-ol, butane-2, 3-diol, D-cellobiose, dextrin, ethanol, *meso*-erythritol, D-fructose, D-fucose, L-fucose, fumaric acid, D-galactose, D-gentiobiose, D-glucose, glycerol, *myo*-inositol, D-lactose, maltose, D-mannitol, D-mannose, D-melezitose, D-melibiose, propane-1, 2-diol, propane-1,3-diol, D-raffinose, D-ribose, D-salicin, sodium acetate, sodium benzoate, sodium *n*-butyrate, sodium propionate, sodium pyruvate, sodium DL-malate, D-sorbitol, sucrose, D-tagatose, trehalose, turanose, D-xylose, and D-xylitol were used as sole carbon sources. The following substrates were not used as sole carbon sources: 3, 3-dimethylglutaric acid, sodium adipate, sodium azelate, sodium citrate, sodium gluconate, sodium malonate, sodium oleate, sodium pimelate, sodium oxalate, sodium sebacate, sodium suberate, or sodium succinate. Acetamide, L-alanine, L-asparagine, L-aspartic acid, L-cysteine, L-glutamic acid, L-glycine, L-histidine, L-leucine, L-isoleucine, DL-norleucine, L-norvaline, L-ornithine, DL-phenylalanine, L-proline, L-serine, L-thymidine, L-valine, and urea were used as sole carbon and nitrogen sources. L-arginine is not used. Acid is produced from D-fructose, but not from D-glucose, D-mannose, D-raffinose, or sucrose. Growth occurs at 37°C but not at 5, 10, or 45°C. Growth occurs pH 7 and 10, but not at pH 5. Growth occurs in the presence of 8% (w/v) NaCl. Growth occurs in the presence of filter paper discs soaked in cephalexin (30 μg/ml), clindamycin hydrochloride (2 μg/ml), colistin (25 μg/ml), erythromycin (5 μg/ml), nalidixic acid (30 μg/ml), novobiocin (5 μg/ml), and tetracycline hydrochloride (10 μg/ml), but not in the presence of bacitracin (10 U), ciprofloxacin (5 μg/ml), cotrimoxazole (25 μg/ml), fusidic acid (10 μg/ml), or penicillin (1 μg/ml).

Source: skin of an immunocompetent patient with confluent and reticulated papillomatosis.

DNA G+C content (mol%): not determined.

Type strain: N 1280, DSM 44961, JCM 15317, NCIMB 14145.

Sequence accession no. (16S rRNA gene): AY643401.

9. **Dietzia psychralcaliphila** Yumoto, Nakamura, Iwata, Kojima, Kusumoto, Nodasaka and Matsuyama 2002, 89[VP]

psy.chral.ca.li′phi.la. Gr. adj. *psychros* cold; N.L. *alcali* alkali, from Arabic *alqali* potash soil; Gr. adj. *philos* friendly to; N.L. fem. adj. *psychralcaliphila* loving cold, alkaline environments.

Aerobic, Gram-stain-positive, nonmotile, non-spore-forming, non-acid-fast, V-forms and rod-shaped cells exhibiting snapping division. Circular, convex, glistening, coral red colonies on TSA plates. Catalase- and oxidase-positive. The cell wall amino acid is *meso*-diaminopimelic acid and the major cell sugars are arabinose and galactose. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{14:0}$ (0.44%), $C_{15:0}$ (1.63%), $C_{16:1}$ *cis*-9 (5.38%), $C_{16:1}$ *cis*-10 (3.78%), $C_{16:0}$ (25.65%), $C_{17:0}$ *cis*-9 (9.26%), $C_{17:0}$ (4.78%), $C_{18:0}$ *cis*-9 (35.55%), 10-methyl $C_{18:0}$ (13.52%). Mycolic acids containing 34–39 carbon atoms are present. The polar lipid profile has not been determined. MK-8(H_2) is the major menaquinone. Growth occurs between 5 and 30°C and between pH 7 and 10, with optimal growth occurring at pH 9–10. Growth occurs in the presence of 12% (w/v) NaCl. Nitrate is not reduced. Voges–Proskauer and methyl red tests are negative. H_2S and indole are not produced. Casein, DNA, gelatin, starch, and urea are not hydrolyzed. Tweens 20, 40, 60, and 80 are hydrolyzed. Utilizes acetate, *n*-butyrate, *n*-eicosane, ethanol, D-fructose, D-glucose, *n*-hexadecane, 3-hydroxybutyrate, isobutyrate, *n*-pentadecane, pristine, propionate, pyruvate, *n*-tetracosane, *n*-tridecane, and valerate, but not *N*-acetylglucosamine, aconitate, L-α-alanine, D-α-alanine, anthracene, D-arabinose, L-arginine, arabitol, L-aspartate, D-cellobiose, caprate, citrate, cyclododecane, *n*-decane, *n*-dotriacontane, *myo*-erythritol, fluorene, fumarate, D-galactose, α-D-galacturonate, glutarate, gluconate, glucuronate, glutamate, 2-oxoglutarate, DL-glycerate, D-glycerol, *p*-histidine, hydroxybenzoate, inositol, DL-lactate, lactose, L-leucine, L-lysine, DL-malate, maltose, mannitol, D-mannose, melibiose, L-ornithine, DL-phenylalanine, L-proline, pyrene, raffinose, rhamnose, D-ribose, salicin, D-sorbitol, succinate, sucrose, L-tartrate, trehalose, L-tyrosine, or D-xylose.

Source: the drain of a fish product processing plant.

DNA G+C content (mol%): 89.6 (HPLC).

Type strain: ILA-1, CCUG 47128, IAM 14896, JCM 10987, NBRC 103065, NCIMB 13777.

Sequence accession no. (16S rRNA gene): AB159036

10. **Dietzia schimae** Li, Zhao, Zhang, Klenk, Pukall, Qin, Xu and Li 2008, 2552[VP]

schi′ma.e. N.L. gen. n. *schimae* of the plant genus *Schima*, isolated from a stem sample of *Schima* sp.

Aerobic, Gram-stain-positive staining, nonmotile, non-spore-forming, non-acid–alcohol-fast, short rods, exhibiting snapping division, and V-forms. Circular, smooth, opaque, deep pink pigmented colonies on TSA plates. Catalase-positive; oxidase-negative. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. Whole-cell fatty acids consist of predominantly straight-chain saturated and unsaturated components, namely $C_{13:0}$ (0.2%), $C_{13:0}$ 3-OH and $C_{15:1}$ iH (0.5%), $C_{14:1}$ ω5*c* (0.2%), $C_{14:0}$ (2.9%), $C_{13:0}$ 2-OH (0.5%), $C_{15:1}$ iso G (0.9%), $C_{15:1}$ A (0.4%), $C_{15:1}$ ω8*c* (0.8%), $C_{15:1}$ ω5*c* (0.4%), $C_{16:1}$ ω6*c*/$C_{16:1}$ ω7*c* (25.8%), 10-methyl $C_{16:0}$ (0.8%), $C_{16:0}$ (22.2%), C17:1 ω7*c* (19.2%), $C_{17:1}$ anteiso B/$C_{17:1}$ iso I (6.8%), 10-methyl $C_{17:0}$ (2.0%), 10-methyl $C_{18:0}$ (13.6%), $C_{19:0}$ iso (1.7%), and $C_{20:0}$ (0.9%). Mycolic acids containing 33–40 carbon atoms are present. The polar lipid profile consists of phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol. MK-8 (H_2) is the major menaquinone. Growth occurs between 10 and 37°C, with optimal growth at 28°C, and between pH 6 and 9, with optimal growth at pH 7. Growth occurs in the presence of 15% (w/v) NaCl. Nitrate is reduced. Voges–Proskauer and methyl red tests are negative. H_2S and indole are not produced. Negative for milk coagulation and peptonization. Gelatin, starch, and urea are not hydrolyzed. Tweens 20, 40, and 80 are hydrolyzed. Esculin, cellobiose, D-fructose, D-glucose, glycerol, D-lactose, D-mannose, and sucrose are used as sole carbon sources. The following substrates are not used as sole carbon sources: D-adonitol, amygdalin, L-arabinose, D-arabinose, D-arabitol, L-arabitol, arbutin, dulcitol, erythritol, D-fucose, L-fucose, D-galactose, gentiobiose, glycogen, inositol, inulin, D-lyxose, maltose, D-mannitol, melezitose, melibiose, methyl-α-D-glucopyranoside, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, *N*-acetylglucosamine, potassium gluconate, potassium 2-ketgluconate,

potassium 5-ketogluconate, raffinose, L-rhamnose, D-ribose, salicin, D-sorbitol, L-sorbose, starch, D-tagatose, trehalose, turanose, xylitol, D-xylose, or L-xylose.

Source: surface-sterilized stem sample of *Schima* sp. collected from Yunnan Province, southwest China.

DNA G+C content (mol%): 71.9 (HPLC).

Type strain: YIM 65001, CCTCC AA 207015, DSM 45139, JCM 16003.

Sequence accession no. (16S rRNA gene): EU375845.

11. **Dietzia timorensis** Yamamura, Lisdiyanti, Ridwan, Ratnakomala, Sarawati, Lestari, Triana, Kartina, Widyastuti and Ando 2010, 452[VP]

ti.mo.ren′sis. N.L. fem. adj. *timorensis* pertaining to West Timor, Indonesia, from where the organism was first isolated.

Aerobic, Gram-stain-positive staining, nonmotile, rod–coccoid shaped cells. Circular, convex, glistening moderately orange-yellow pigmented colonies. The cell-wall amino acid is *meso*-diaminopimelic acid and the major cell-wall sugars are arabinose and galactose. The major cellular fatty acids are $C_{16:0}$ (48%), $C_{18:1}$ ω9*c*, and 10-methyl $C_{18:0}$ (8%). Mycolic acids containing 34–38 carbon atoms are present. The polar lipid profile consists of phosphatidylglycerol, and trace amounts of phosphatidylinositol. Growth occurs between 10 and 37°C, but not at 5 or 45°C. Growth occurs in the presence of 7% (w/v) NaCl. Esculin is hydrolyzed. Nitrate is not reduced. Arbutin and urea are not hydrolyzed. Does not degrade adenine, casein, elastin, hypoxanthine, testosterone, tyrosine, uric acid, or xanthine. Utilizes esculin, cellobiose, D-fructose, D-glucose, glycerol, lactose, D-mannose, sucrose, D-adonitol, amygdalin, L-arabinose, D-arabinose, L-arabitol, D-arabitol, arbutin, dulcitol, erythritol, L-fucose, D-fucose, D-galactose, gentiobiose, glycogen, inositol, inulin, D-lyxose, maltose, D-mannitol, melezitose, melibiose, methyl-α-D-glucopyranoside, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, *N*-acetylglucosamine, potassium gluconate, potassium 2-ketogluconate, potassium 5-ketogluconate, raffinose, L-rhamnose, D-ribose, salicin, D-sorbitol, L-sorbose, starch, D-tagatose, trehalose, turanose, xylitol, L-xylose, and D-xylose.

Source: soil sample collected from under mahogany (*Swietenia mahogani*) trees on West Timor in Indonesia.

DNA G+C content (mol%): 65.5 (HPLC).

Type strain: ID05-A0528, BTCC B-560, NBRC 104184.

Sequence accession no. (16S rRNA gene): AB377289.

Family III. **Mycobacteriaceae** Chester 1897, 63[AL]

John G. Magee and Alan C. Ward

My.co.bac.te.ri.a.ce′a.e. N.L. neut. n. *Mycobacterium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Mycobacteriaceae* the *Mycobacterium* family.

The family contains the type genus *Mycobacterium*. The phylogenetic position of the family *Mycobacteriaceae*, as determined by 16S rRNA gene sequence analysis, is in the order *Corynebacteriales*.

Genus I. **Mycobacterium** Lehmann and Neumann 1896, 363[AL]

John G. Magee and Alan C. Ward

My.co.bac.te′ri.um. Gr. n. *mukês* a fungus; L. neut. n. *bacterium*, a small rod; N.L. neut. n. *Mycobacterium* a fungus rodlet.

Aerobic to microaerophilic, slightly curved or straight rods (0.2–0.6 × 1.0–10 µm), **which are acid–alcohol-fast at some stage of growth**. Most species are difficult to stain by Gram's method, but are usually considered Gram-stain-positive. Branching may sometimes occur and a filamentous or mycelium-like growth may appear which, on slight disturbance, becomes fragmented into rods or coccoid elements. **Cells are nonmotile and asporogenous; conidia or capsules are not produced; there are no grossly visible aerial hyphae. Colonies may be white- to cream-colored; some strains produce yellow- or orange-pigmented colonies with or without light stimulation. Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid, arabinose, and galactose. The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-glycolated. Cells and cell walls are rich in lipids. These include waxes which have characteristic, chloroform-soluble, mycolic acids with long (60–90 carbon atoms) branched chains. The fatty acid esters released on pyrolysis MS of mycolic acid esters have 22–26 carbon atoms. Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phospatidylinositol mannosides as predominant polar lipids, straight-chain saturated, unsaturated, and 10-methyloctadecanoic (tuberculostearic) fatty acids as major fatty acid components, and dihydrogenated menaquinones with nine isoprene units as the predominant isoprenolog.** The genus includes obligate parasites, saprophytes, and opportunistic forms.

DNA G+C content (mol%): 57–73 (T_m; HPLC; whole-genome sequencing).

Type species: **Mycobacterium tuberculosis** (Zopf 1883) Lehmann and Neumann 1896, 363[AL].

Further descriptive information

Phylogeny. The family *Mycobacteriaceae* contains the type genus *Mycobacterium* Lehmann and Neumann (1896). Initially, the genus was proposed to include the tubercle and leprosy bacilli. Subsequently, many more mycobacterial species were proposed, although only 41 species were included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). At the time of writing, there were 129 species and subspecies with validly published names classified in the genus (Table 35). Most mycobacterial species can be assigned to two taxonomic groups based on growth rate. For practical determinative purposes, slow-growing species require 7 or more days of incubation at optimal temperature to produce easily seen colonies from highly dilute inocula. Conversely, rapid-growing species are seen in less than 7 d under comparable conditions (Wayne and Kubica, 1986). Clinically relevant species are more likely, although not exclusively, to occur in the slow-growing group (Goodfellow and Magee, 1998). Phylogenies based on 16S rRNA gene similarity studies suggest that this division is a natural one (Fox and Stackebrandt, 1987; Goodfellow and Magee, 1998; Rogall et al., 1990; Stahl and Urbance, 1990).

There is some association between the number of ribosomal operons and the growth rate of mycobacterial strains. Bercovier et al. (1986) showed that fast-growing strains commonly have two operons (*rrnA* and *rrnB*), whereas slow-growing strains usually have one. The mycobacterial operon is composed of a leader region, a 16S rRNA gene, intergenic spacer-1 (ITS-1), a 23S rRNA gene, ITS-2, and a 5S rRNA gene (Ji et al., 1994a). The sizes of the leader and spacer regions vary between fast- and slow-growing mycobacteria (Ji et al., 1994b). This latter study led to the proposal that slow-growing species separated from the main phyletic line following the deletion of a DNA segment which spanned an *rrnB*-like operon, leaving an *rrnA*-like operon as the sole source of rRNA. The leader and spacer regions of rrn operons are highly conserved and have occasionally proved useful in further assessing phylogenetic relationships between closely related mycobacterial species.

Tsukamura (1967c) proposed the separation of fast-growing mycobacteria into a new subgenus *Mycomycobacterium*. However, rapid- and slow-growing mycobacteria share too many properties in common, as exemplified by their antigenic composition (Chaparas et al., 1978a, 1978b; Stanford and Grange, 1974), bacteriophage susceptibility (Froman et al., 1954), DNA homology (Baess and Bentzon, 1978; Bradley, 1973; Gross and Wayne, 1970), and lipid composition (Minnikin and Goodfellow, 1980a, 1980b; Minnikin et al., 1980) to justify their separation into two subgenera.

Phylogenetic analyses of 16S rRNA gene sequence data show that mycolic acid-containing actinomycetes form a well-defined clade within the order *Corynebacteriales* (formerly suborder *Corynebacterineae* (Stackebrandt et al., 1997). Mycobacteria form a distinct phyletic line within this clade. Using these data, the constituent genera have been assigned to the families *Corynebacteriaceae* (encompassing *Corynebacterium* and *Dietzia*),

Mycobacteriaceae (*Mycobacterium*), and *Nocardiaceae* (encompassing *Gordonia*, *Nocardia*, *Rhodococcus*, and *Tsukamurella*) (Goodfellow and Magee, 1998). However, Stackebrandt et al. (1997) proposed a new hierarchic classification based on the presence of key signature nucleotides, a concept that was further developed by Zhi et al. (2009). Though again placing the mycolic acid-containing actinomycetes within the order *Corynebacteriales*, each of the constituent taxa, namely the families *Corynebacteriaceae* (encompassing *Corynebacterium* and *Turicella*), *Dietziaceae*, *Mycobacteriaceae*, *Nocardiaceae* (encompassing *Gordonia*, *Nocardia*, *Millisia*, *Rhodococcus*, *Skermania*, and *Williamsia*), *Segniliparaceae*, and *Tsukamurellaceae*, were circumscribed by the presence of a characteristic pattern of nucleotides at defined positions on the 16S rRNA gene. The family *Mycobacteriaceae* was defined by a pattern of 16S rRNA gene signatures which consisted of nucleotides at positions 128:233 (G–C), 250 (U), 316:337 (C–G), 418:425 (C–G), 586:755 (U–G), 599:639 (U–G), 662:743 (C–G), 987:1218 (G–C), 1000:1040 (A–U), and 1026:1035 (U–G).

Cell morphology. Cell growth is slow or very slow with cell generation times ranging from 2 h to more than 20 h (David, 1973). Incubation periods of only a few days or over 8 weeks may be needed for a dilute inoculum to produce easily visible colonies on solid media at optimal temperatures. Optimal temperatures vary widely according to the species, ranging from well below ambient to over 45°C. Most species adapt readily to growth on very simple substrates, using amino acids or ammonia as nitrogen sources and glycerol as a carbon source in the presence of mineral salts. Some fastidious organisms require supplements, such as hemin (*Mycobacterium haemophilum*), mycobactins (*Mycobacterium avium* subsp. *paratuberculosis*), or other iron transport compounds. *Mycobacterium leprae* has not been cultivated outside living cells.

Cell-wall composition. The cell-wall peptidoglycolipid contains *meso*-diaminopimelic acid, alanine, glutamic acid, glucosamine, muramic acid, arabinose, and galactose (wall chemotype type IV *sensu* Lechevalier and Lechevalier, 1970). Resistance to decolorization by an acid–alcohol mixture following staining with basic fuchsin is a characteristic feature of mycobacteria and some closely related actinomycetes. This property may be related to the lipid barrier of the wall mycolyl-arabinogalactan impeding the penetration of the decolorizing agent. Variations in wall lipid content may account for differences in the degree of acid-fastness between mycobacterial species.

The lipid content of mycobacterial cells and cell walls is high (Minnikin and Goodfellow, 1980b). Wall chemotype IV actinomycetes, including mycobacteria, contain mycolic acids, which are high-molecular-mass, long chain, 3-hydroxy fatty acids with an aliphatic side chain at position 2. Non-mycobacterial mycolic acids vary in chain length (22–74 carbons) and in the number of double bonds (0–5). Mycobacterial mycolates have between 60 and 90 carbon atoms, occur in a variety of structural types, and do not have more than two points of unsaturation (Minnikin and Goodfellow, 1980b). Mycobacterial species can be assigned to one of several groups based on the presence or absence of different functional groups, as detected by TLC of methanolysates (Table 36; Goodfellow and Magee, 1998). Pyrolysis of mycobacterial mycolic acid methyl esters yields long-chain

TABLE 36. Grouping of mycobacteria based on mycolic acid patterns[a]

[a]Adapted from Dobson et al. (1985) and Goodfellow and Magee (1998) to include data from: Apajalahti et al. (1986), Ausina et al. (1992), Böttger et al. (1993), Butler et al. (1993), Derz et al. (2004), Domenech et al. (1997), Fanti et al. (2004), Floyd et al. (2000), Haas et al. (1997), Häggblom et al. (1994), Jiménez et al. (2004), Kazda et al. (1990, 1992, 1993), Kirschner et al. (1992), Kleespies et al. (1996), Koukila-Kähkölä et al. (1995), Lévy-Frébault et al. (1986a), Luquin et al. (1993), Meier et al. (1993), Padgitt and Moshier (1987), Reischl et al. (1998, 2006), Richter et al. (2002), Roth et al. (2000), Schröder et al. (1997), Shojaei et al. (1997, 2000), Springer et al. (1993, 1995a, 1995b, 1996c), Tortoli et al. (1999, 2001, 2004, 2005), Trujillo et al. (2004), Tsukamura et al. (1986c), Valero-Guillén et al. (1988), Vuorio et al. (1999), Willumsen et al. (2001), and Yassin et al. (1993).

[b]Wax ester mycolates are composed of ω-carboxymycolates esterified to 2-eicosanol and homologs.

fatty acid methyl esters (C_{22} to C_{26}); shorter chain methyl esters are derived from other mycolic acid-containing actinomycetes (Minnikin and Goodfellow, 1980b).

Polar lipid composition can yield valuable information for the classification and identification of actinomycetes (Goodfellow, 1989). The most common polar lipid types are the phospholipids. Lechevalier et al. (1981) classified actinomycetes into five phospholipid groups based on semi-quantitative analyses of the major lipid markers found in whole-organism extracts. The most common phospholipids found in mycobacteria are derivatives of phosphatidic acid. Mycobacteria typically contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides (Goodfellow and Magee, 1998; Minnikin, 1982).

Menaquinones are the most common type of isoprenoid quinone found in actinomycetes (Collins, 1994). These compounds are classified according to the length of their isoprenyl side chain, which can vary from one up to 15 isoprene units, and in the degree of saturation or hydrogenation of the C_5 isoprenyl side chain. *Corynebacterium*, *Gordonia*, and *Mycobacterium* strains contain dihydrogenated menaquinones with nine isoprene units as the main component [abbreviated as MK-9(H_2); Collins, 1994] and can thereby be differentiated from the other mycolic acid-containing taxa (see section under the order *Corynebacteriales*).

Colony morphology. Most mycobacteria form more than one kind of colony, but colonies of some species, such as *Mycobacterium intracellulare*, are usually smooth on primary isolation from clinical specimens. Cells of rough strains are usually compacted in curving strands; those of smooth strains are not visibly oriented in any pattern. Some colonies, such as those of *Mycobacterium fortuitum* and *Mycobacterium xenopi*, may be mycelial in early stages of growth, but older colonies exhibit branching filamentous extensions on and into media such as cornmeal glycerol agar; fragmentation to bacillary forms usually occurs as a result of smear preparation. However, *Mycobacterium farcinogenes* and *Mycobacterium senegalense* differ from other mycobacteria in the formation of a stable mycelium (Chamoiseau, 1973, 1979). Aerial filamentous extensions are never visible without magnification (×30–100). Many strains produce white- to cream-colored colonies. However, the presence of carotenoid pigments in some strains leads to the formation of yellow- or orange-colored (rarely pink) colonies. Such pigmentation may only be produced when growth is exposed to light (photochromogenic species) or may develop in darkness without light stimulation (scotochromogenic species). Diffusible pigments are rarely found.

Nutrition, growth conditions and metabolism. Most mycobacteria are obligate aerobes, although some species tolerate reduced oxygen levels. Carbon dioxide is also necessary for growth and is obtained either from the atmosphere or from growth supplements. Mycobacteria show considerable variation in substrates used as sources of carbon and nitrogen. Such variations can be used as an aid to species identification (see below). Additional growth requirements include iron salts, magnesium, potassium, sodium, and sulfur. Though the growth of many species is supported by simple media, such as modified Sauton's agar (Mordarska et al., 1972), cultivation of clinically significant mycobacteria is better with egg-based media, notably Löwenstein–Jensen (Jensen, 1932; Löwenstein, 1931) or Middlebrook media (Lorian, 1968). Some species need complex supplements; for instance, *Mycobacterium haemophilum* requires growth media to be supplemented with 0.4% hemoglobin or 60 µM hemin (Sompolinsky et al., 1978).

In most respects, the metabolism of mycobacteria is common to that of other bacteria, although some features are more typical of this genus than others. Glycerol is a common constituent of growth media since most mycobacterial species efficiently metabolize it to pyruvate; one exception is *Mycobacterium bovis*, which grows better in media containing pyruvate (Stonebrink, 1958). Similarly, asparagine is a valuable nitrogen source and is included as a constituent in most standard media used to cultivate mycobacteria. Acquisition of iron is vital to most bacteria and, in living tissues, successful competition with iron-binding proteins of the host may be a marker of pathogenicity. Unusually, mycobacteria possess two types of siderophores (iron-chelating agents): exochelins, which are secreted from the cell; and mycobactins, which are cell-wall-bound (Ratledge, 1984). Mycobactins are hydroxamate compounds produced by all mycobacteria, except *Mycobacterium avium* subsp. *paratuberculosis* (Bergey et al., 1923).

Genetics and whole-genome sequence analyses. One of the first micro-organisms subjected to whole-genome sequencing was *Mycobacterium tuberculosis* H_{37}Rv (Cole et al., 1998). Subsequently, the genomes of other members of the *Mycobacterium tuberculosis* complex and representatives of several other mycobacterial species have been, or are being, sequenced. However, despite this, the impact of whole-genome sequencing on the taxonomy of the genus *Mycobacterium* is currently limited and somewhat biased given the choice of strains. Strains have been selected for whole-genome sequencing in response to biological questions (Cole et al., 1998), pathogenicity determinants (Fleischmann et al., 2002), vaccine efficacy (Brosch et al., 2007), and in the search for novel antibiotic targets (Cole, 2002). The expectation that whole-genome sequences would provide clear-cut data for the construction of a taxonomic framework for mycobacteria has been undermined by the sheer complexity of the acquired data. Nevertheless, the availability of mycobacterial whole-genome sequences highlights changes which are shaping the diversity of these organisms. Rearrangement of gene content occurs due to the acquisition or loss of DNA through gene duplication and horizontal gene transfer, and the elimination of genes that do not give any selective advantage (Kuo and Ochman, 2009). These factors influence mycobacterial speciation (Cole et al., 2001; Garnier et al., 2003).

The importance of gene loss in virulence and host specificity is revealed in the genome of *Mycobacterium leprae* which, compared to that of *Mycobacterium tuberculosis*, has lost over 2000 genes with over 1000 being identified as pseudo-genes, that is, defective genes not yet completely deleted (Cole et al., 2001). Gene loss seems to be a factor in the evolution of *Mycobacterium tuberculosis* and in the ongoing evolution of host specificity in other members of the *Mycobacterium tuberculosis* complex (Garnier et al., 2003; Stinear et al., 2004, 2007).

The evolutionary bottleneck leading to *Mycobacterium tuberculosis* from an ancestral "*Mycobacterium canettii*" has been largely reconstructed from gene deletion analysis (Brosch et al., 2002). Progress in whole-genome sequencing of members of

the *Mycobacterium tuberculosis* complex and of "*Mycobacterium canettii*" will "add grist to the mill", as it has for unraveling the evolution of *Mycobacterium bovis* (Smith et al., 2006). Similarly, whole-genome sequence analysis suggests that *Mycobacterium avium* subsp. *avium*, *Mycobacterium avium* subsp. *paratuberculosis*, and *Mycobacterium avium* subsp. *silvaticum* are undergoing parallel evolutionary development from a different environmental/pathogenic precursor, "*Mycobacterium avium* subsp. *hominissuis*" (Li et al., 2005; Turenne et al., 2007). The latter is an environmental organism with a large genome and evidence of much genetic diversity. Two groups of specialist pathogens are evolving from this genetic pool, namely those of birds (*Mycobacterium avium* subsp. *avium*, *Mycobacterium avium* subsp. *silvaticum*) and of ruminants (*Mycobacterium avium* subsp. *paratuberculosis*). These organisms, like members of the *Mycobacterium tuberculosis* complex, show a pattern of phenotypic diversity and genome reduction, but high clonality and strong homology with the ancestral genome (Turenne et al., 2007).

A notable example of such genomic changes is provided by *Mycobacterium ulcerans*. The recent evolution and changing ecological niche and host specificity of this species is being driven by massive gene loss as the organism diverges from *Mycobacterium marinum* (Stinear et al., 2004; Stinear et al., 2007). *Mycobacterium ulcerans* has acquired the plasmid *p*mum001, the insertion sequences IS*2404* and IS*2606*, and the plasmid-encoded polyketide synthases required to synthesize the mycotoxin mycolactone (Stinear et al., 2004). These genomic elements are driving gene rearrangements, inactivation, and deletions so that the genome of *Mycobacterium marinum* contains 6.63 Mb and that of *Mycobacterium ulcerans* 5.63 Mb (Stinear et al. 2007, 2008). The novel genetic trait of mycotoxin biosynthesis is still being exploited and diversified in different lineages of *Mycobacterium marinum* and *Mycobacterium ulcerans* (Kaser et al., 2007; Stinear et al., 2005). About 90% of the protein-coding genes in *Mycobacterium ulcerans* are syntenic orthologs of the corresponding genes in *Mycobacterium marinum* with a mean identity of >98%; the 16S rRNA gene has a single base difference present in all strains and one other base differing in some strains (>99.8% similarity). Nevertheless, the two species are phenotypically distinct and give <40% similarity in DNA–DNA pairing analyses (Stinear et al., 2004; Stinear et al., 2007).

It can be concluded that whole-genome analyses are revealing taxonomic inconsistencies and the complexity of mycobacterial species. In general, the increasing availability of whole-genome sequences can be considered as a step towards a genomic taxonomy (Achtman and Wagner, 2008; Coenye et al., 2005).

Phage susceptibility. Bacteriophages lytic for many mycobacteria, including *Mycobacterium tuberculosis* strains, have been isolated by using soil enrichment techniques (Froman et al., 1954). Lysogenic (Russell et al., 1964) and plasmid-bearing (Crawford et al., 1981a) mycobacteria have been found in nature. Many investigators have tried to use phage typing as a taxonomic tool, but poor inter-laboratory reproducibility and the ability of phages to cross species lines have limited its value. However, phage patterns within the species *Mycobacterium tuberculosis* have been found useful for epidemiological studies (Baess, 1969; Bates and Mitchison, 1969; Jones et al., 1982). Bacteriocins have been detected in mycobacteria and used in the classification of some species (Takeya and Tokiwa, 1972).

Antigenic structure. Although now seldom used, antigenic analyses have proven valuable at several hierarchical levels. Ribosomal proteins are conserved within the genus and immunodiffusion analyses have been used to compare members of the genus *Mycobacterium* with those of closely allied taxa (Ridell et al., 1979). Analyses of immunodiffusion and immunoelectrophoretic patterns of whole-cell filtrates and extracts have provided useful data for defining species within the genus (Chaparas et al., 1978a; Norlin, 1965; Stanford and Grange, 1974), as have quantitative comparisons of skin hypersensitivity reactions of sensitized guinea pigs to crude culture filtrates of homologous and heterologous mycobacteria (Magnusson, 1980). Seroprecipitation studies of mycobacterial catalase have been used to establish immunological distances between species, as an indirect measure of evolutionary divergence (Wayne and Diaz, 1982). Whole-cell seroagglutination reactions, based on peptidoglycolipid surface antigens, usually differentiate strains at the infra-subspecific level (Brennan, 1981; Schaefer, 1967), though some species appear to comprise single serovars (Wayne, 1971).

Antibiotic or drug susceptibility. In the absence of genomic mutations conferring resistance, *Mycobacterium tuberculosis* is susceptible to a range of chemotherapeutic agents. Though all populations of *Mycobacterium tuberculosis* contain some mutant organisms, it is generally held that a strain is susceptible to a particular chemotherapeutic agent when such mutants comprise less than 1% of all cells present in an *in vitro* culture. Conversely, when the proportion of mutants is found to be greater than 1%, these strains will become dominant if the drug concerned is used in therapy (Middlebrook and Cohn, 1953). In order to ensure effectiveness of therapy and to reduce the duration of treatment, chemotherapy of tuberculosis is based on the use of combinations of several drugs, to which the strain is known to be susceptible, usually delivered in a two-phase strategy (Fox, 1968; Mitchinson and Dickinson, 1978).

Standard treatment will commonly involve the chemotherapeutic agents isoniazid and rifampin, supplemented with pyrazinamide and either ethambutol or streptomycin during the initial intensive phase. As a result, *in vitro* susceptibility testing of isolated strains is usually focused on these agents. However, a number of issues may force modifications of drug regimes in resource-poor countries (International Union Against Tuberculosis and Lung Disease, 1988, 1993). These factors, together with the development of drug resistance in some strains, mean that other chemotherapeutic agents (e.g. WHO quinolones and thiacetazone) may occasionally be tested (Shimao, 1998). Additionally, species of mycobacteria other than those encompassed in the *Mycobacterium tuberculosis* complex (non-tuberculous mycobacteria) may be implicated in disease and require specific drug treatments. Although standard anti-tuberculosis chemotherapeutic agents are still used in the treatment of infections due to non-tuberculous mycobacteria, when tested *in vitro* against these agents these species are often found to be resistant. However, synergistic activity can sometimes be detected between combinations of agents (Banks and Jenkins, 1987). Furthermore, conventional antibiotics such as macrolides may prove to have activity against some non-tuberculous mycobacteria, notably rapid-growing species (Campbell et al., 1998).

Pathogenicity. The genus includes obligate and opportunistic parasites and saprophytes. All mycobacteria produce

granulomatous lesions in experimental animals if a sufficiently large inoculum is used (Wayne and Kubica, 1986). However, only some species grow in host tissues and produce progressive or self-limiting disease. Individual species may be pathogenic for cold-blooded animals, mammals, and/or birds. The site of infection varies with the mycobacterial species, some show a predilection for internal organs, especially lungs, and others are less invasive and cause skin surface lesions. Major disease syndromes include leprosy and tuberculosis.

Ecology. Most mycobacterial species are free-living in soil and water. However, the major ecological niche for some mycobacteria is diseased tissue of warm-blooded hosts. Although most human infections are due to either *Mycobacterium leprae* or *Mycobacterium tuberculosis*, it has long been recognized that members of other mycobacterial species may be opportunistic pathogens of humans. This is particularly so in immunocompromised individuals. Many animals, including aquatic, bird, and surface-dwelling species, may be hosts to mycobacterial species.

Enrichment and isolation procedures

The presence of a mixed flora in clinical samples, soil, water, and some other environmental sources means that the isolation of mycobacteria requires sample decontamination. This is attempted with agents that selectively kill non-acid-fast contaminants. Suitable agents include dilute acids or alkalis, with or without quaternary ammonium compounds, followed by neutralization. Time of exposure to decontaminating agents must be carefully controlled, as resistance of mycobacteria is not absolute (Krasnow and Wayne, 1966). Decontaminated specimens are inoculated onto agar media, inspissated egg media, or into liquid culture media; media may also be supplemented with selective antimicrobial agents. Although now rarely applied, an alternative method is to inject liquefied specimens into guinea pigs or mice; pure cultures can be obtained from their internal organs after 2–3 weeks.

Maintenance procedures

Strains will remain viable on egg medium held at 5°C for many months and will survive indefinitely at −70°C or after lyophilization. Most species are readily subcultured on inspissated egg medium, Dubos' oleic acid-albumin, or Middlebrook 7H10 or 7H11 agar, and in liquid media containing Tween 80 for dispersal and bovine serum albumin to neutralize traces of oleic acid. Laboratory-adapted strains often grow well on synthetic media containing asparagine, glycerol, and mineral salts.

Taxonomic comments

The taxonomic history of the genus *Mycobacterium* is difficult to disentangle from that of related taxa, notably from the genera *Corynebacterium*, *Nocardia*, and *Rhodococcus* (Bousfield and Goodfellow, 1976). The intricacies of the pioneering studies on these genera can be gleaned from one or more comprehensive review articles (Barksdale and Kim, 1977; Goodfellow and Magee, 1998; Goodfellow and Minnikin, 1977, 1984).

Early work on the taxonomy of mycobacteria was dominated by clinical interest, which promoted a tendency to see different types of mycobacteria in terms of their relationships with *Mycobacterium tuberculosis*. This unfortunate, but understandable, skew was reflected in the common use of the term "atypical mycobacteria" for strains that could not be identified as either *Mycobacterium bovis* or *Mycobacterium tuberculosis*. Indeed, it was not until the mid-1950s that a much-needed classification was introduced for mycobacteria by Ernest Runyon and his colleagues (Runyon, 1958, 1959; Timpe and Runyon, 1954). In Runyon's classification, mycobacteria, with the exception of those in the *Mycobacterium tuberculosis* complex and members of uncultivable taxa, were divided into four overtly artificial groups based on growth rates and pigmentation properties. Runyon's Groups I, II, and III were composed of slow-growing strains of mycobacteria, with Group IV containing the rapid growers. The acceptance of Runyon's Groups by the clinical community was a defining moment in the development of mycobacterial systematics, one brilliantly captured in a review article by Wayne (2000).

The seminal studies of Runyon and his colleagues paved the way for more exacting taxonomic investigations as it was soon realized that Runyon's Groups were heterogeneous. Ruth Gordon and her colleagues (Gordon and Mihm, 1959; Gordon and Smith, 1953, 1955) classified rapid-growing mycobacteria not on the basis of a few subjectively weighted phenotypic properties but on overall similarities, in essence, a numerical taxonomic approach without the use of computers. However, initial attempts to classify slow-growing mycobacteria using standard phenotypic tests merely reaffirmed the limited differences afforded by Runyon's Groups I to III.

Wayne (1967) broke the impasse outlined above by introducing a portfolio of phenotypic tests which were suitable for the classification of slow-growing mycobacteria. He went on to be the motive force behind a series of studies designed to clarify relationships between both established and novel mycobacterial species, and to highlight properties for the recognition of clinically significant slow-growing species. A coordinated series of well-planned taxonomic studies carried out under the auspices of the International Working Group on Mycobacterial Taxonomy (IWGMT) led to significant improvements in the classification of fast-growing (Goodfellow et al., 1974; Kubica et al., 1972) and slow-growing mycobacteria (Meissner et al., 1974; Wayne et al., 1971, 1978, 1981, 1983, 1989, 1991). Phenotypic data acquired in some of these investigations were used in subsequent IWGMT studies to produce a panel of reproducible tests (Wayne et al., 1974, 1976) for the generation of frequency matrices designed to facilitate the accurate identification of clinically significant slow-growing mycobacteria (Wayne et al., 1980).

The use of a combination of taxonomic criteria in the IWGMT studies was instrumental in placing mycobacterial systematics on a sound footing, notably for the benefit of the clinical community (Wayne, 2000). Nevertheless, several slow-growing mycobacterial taxa remained ill-defined, a problem which was addressed in the final IWGMT study (Wayne et al., 1996). In this investigation, slow-growing mycobacteria that did not fit into any of the species that had been adequately characterized in earlier IWGMT studies were analyzed using a combination of chemotaxonomic and molecular systematic procedures, including 16S rRNA gene sequencing and DNA–DNA pairing studies. In general, good overall agreement was

found between the resultant phenotypic clusters and groups of organisms circumscribed using the molecular procedures. Wayne and his colleagues concluded that polyphasic taxonomy provided a satisfactory way to resolve relationships between members of the genus *Mycobacterium*.

Polyphasic taxonomy is now universally practiced in the delineation of novel *Mycobacterium* species. The taxonomic relationships of both putatively novel and poorly classified mycobacteria can be determined readily by comparing their 16S rRNA gene sequences with those of corresponding mycobacterial species held in 16S rRNA gene databases. Indeed, many recent novel *Mycobacterium* species have been delineated using 16S rRNA gene sequence and associated phenotypic data, as exemplified by proposals for *Mycobacterium bohemicum* (Reischl et al., 1998), *Mycobacterium elephantis* (Shojaei et al., 2000), and *Mycobacterium novocastrense* (Shojaei et al., 1997).

16S rRNA molecules from members of closely related mycobacterial taxa may be so conserved that they cannot be used to differentiate between them at the species level. In such instances, DNA–DNA pairing remains the method of choice as it gives a higher resolution than corresponding 16S rRNA gene sequencing data (see Adékambi et al., 2006a). Kusunoki and Ezaki (1992) used a number of DNA–DNA pairing techniques to clarify the taxonomy of members of the *Mycobacterium fortuitum* complex. These and associated studies led to the proposal to reinstate *Mycobacterium peregrinum* as a distinct species and for *Mycobacterium chelonae* subsp. *abscessus* to be given species status as *Mycobacterium abscessus*.

The fact that DNA–DNA pairing studies tend to be hampered by technical difficulties led some workers to clarify relationships between closely related taxa by using sequence data generated from genes less well conserved than the 16S rRNA gene. The description of *Mycobacterium conceptionense*, for example, was to a considerable extent based on the results of a partial *rpoB* gene sequence analysis which allowed this species to be clearly separated from *Mycobacterium porcinum*, its nearest phylogenetic neighbor (Adékambi et al., 2006c). Similarly, *rpoB* sequence data proved to be invaluable in distinguishing *Mycobacterium aubagnense* and *Mycobacterium phocaicum* from one another and from their phylogenetic neighbor *Mycobacterium mucogenicum* (Adékambi et al., 2006a), as well as delineating *Mycobacterium salmoniphilum* from *Mycobacterium chelonae* (Whipps et al., 2007). Closely related taxa have also been distinguished using ITS sequences, as in the case of proposals for the recognition of *Mycobacterium heckeshornense* (Roth et al., 2000) and *Mycobacterium monacense* (Reischl et al., 2006), and by using a multigene approach as applied to the classification of *Mycobacterium doricum* by Devulder et al. (2005).

The increasingly varied phylogenetic approaches that are being adopted for the circumspection of mycobacterial species makes comparison between them difficult, especially in instances where inadequate phenotypic data are provided. Such *ad hoc* approaches, which run counter to the IWGMT philosophy, risk eroding the road to taxonomic consensus that has prevailed in recent times. One way forward would be to update the minimal standards for the description of novel slow-growing *Mycobacterium* species (Lévy-Frébault and Portaels, 1992) and for the introduction of corresponding minimal standards for the recognition of fast-growing *Mycobacterium* species. To such ends, key phenotypic characteristics should be acquired from procedures for determining growth rate, growth temperature (both range and optimum), colony morphology, pigmentation (type and color), and, for rapid-growers, NaCl tolerance and growth on MacConkey agar. Analyses of mycolic acids by HPLC and/or TLC also provide valuable taxonomic data, as do fatty acid analyses (Goodfellow and Magee, 1998). Guidance is also needed on which molecular systematic approaches should be recommended in addition to 16S rRNA gene sequencing.

Differentiation of the genus *Mycobacterium* from other genera

The genus *Mycobacterium* can be differentiated from other mycolic acid-containing genera using a combination of chemotaxonomic and morphological markers (see section on the order *Corynebacteriales*) and by the possession of unique 16S rRNA nucleotide signatures (see below). In addition, the type strains of most *Mycobacterium* species can be distinguished by their 16S rRNA gene sequences and phylogeny as seen in Figure 86 and Figure 87.

Differentiation of species within the genus *Mycobacterium*

Very few phenotypic characters underpin the separation of rapid- and slow-growing mycobacteria. Differences in resistance to decolorization by alkali of bacilli stained with neutral red suggest variation in lipid composition between rapid- and slow-growing species; slow-growers showing greater resistance (Wayne, 1959). Similarly, acid–alcohol-fastness after staining with basic fuchsin (see below) tends to be a stronger attribute in slow-growing mycobacteria. The uptake of iron from an iron-rich medium is more likely to be a property of rapid-growing species (Wayne, 1967), as is growth in the presence of 5% (w/v) NaCl (Kubica et al., 1970) and 0.2% (w/v) picrate (Wayne and Kubica, 1986). None of these characteristics are exclusive markers of growth rate, but practical experience has demonstrated that different sets of tests are necessary for characterizing rapid- and slow-growing mycobacterial species. Members within the two groups can be distinguished using a combination of phenotypic properties (Table 37 and Table 38).

Phylogenetic trees were constructed using 16S rRNA gene sequence data (Figure 86 and Figure 87). Wherever possible, sequence data were taken from original species descriptions. However, as emphasized by Stackebrandt et al. (2002), high quality rRNA gene sequence data are needed to determine phylogenetic relationships; hence, in some cases, high quality sequence data were taken not from the original study but from a subsequent one. Nevertheless, sequences derived from type strains were used for all but a few species. For the species, *Mycobacterium haemophilum*, *Mycobacterium sphagni*, and *Mycobacterium ulcerans*, type strain sequences were all of short lengths. In these cases longer sequences derived from representative strains were validated by matching against the available sequence data of the type strain, and then used in the generation of phylogenetic trees. Two sequences were available for the type strain of *Mycobacterium peregrinum*; the sequence selected was that which best matched the phylogeny to the phenotypic characteristics. The sequence data were aligned using CLUSTAL X (Thompson

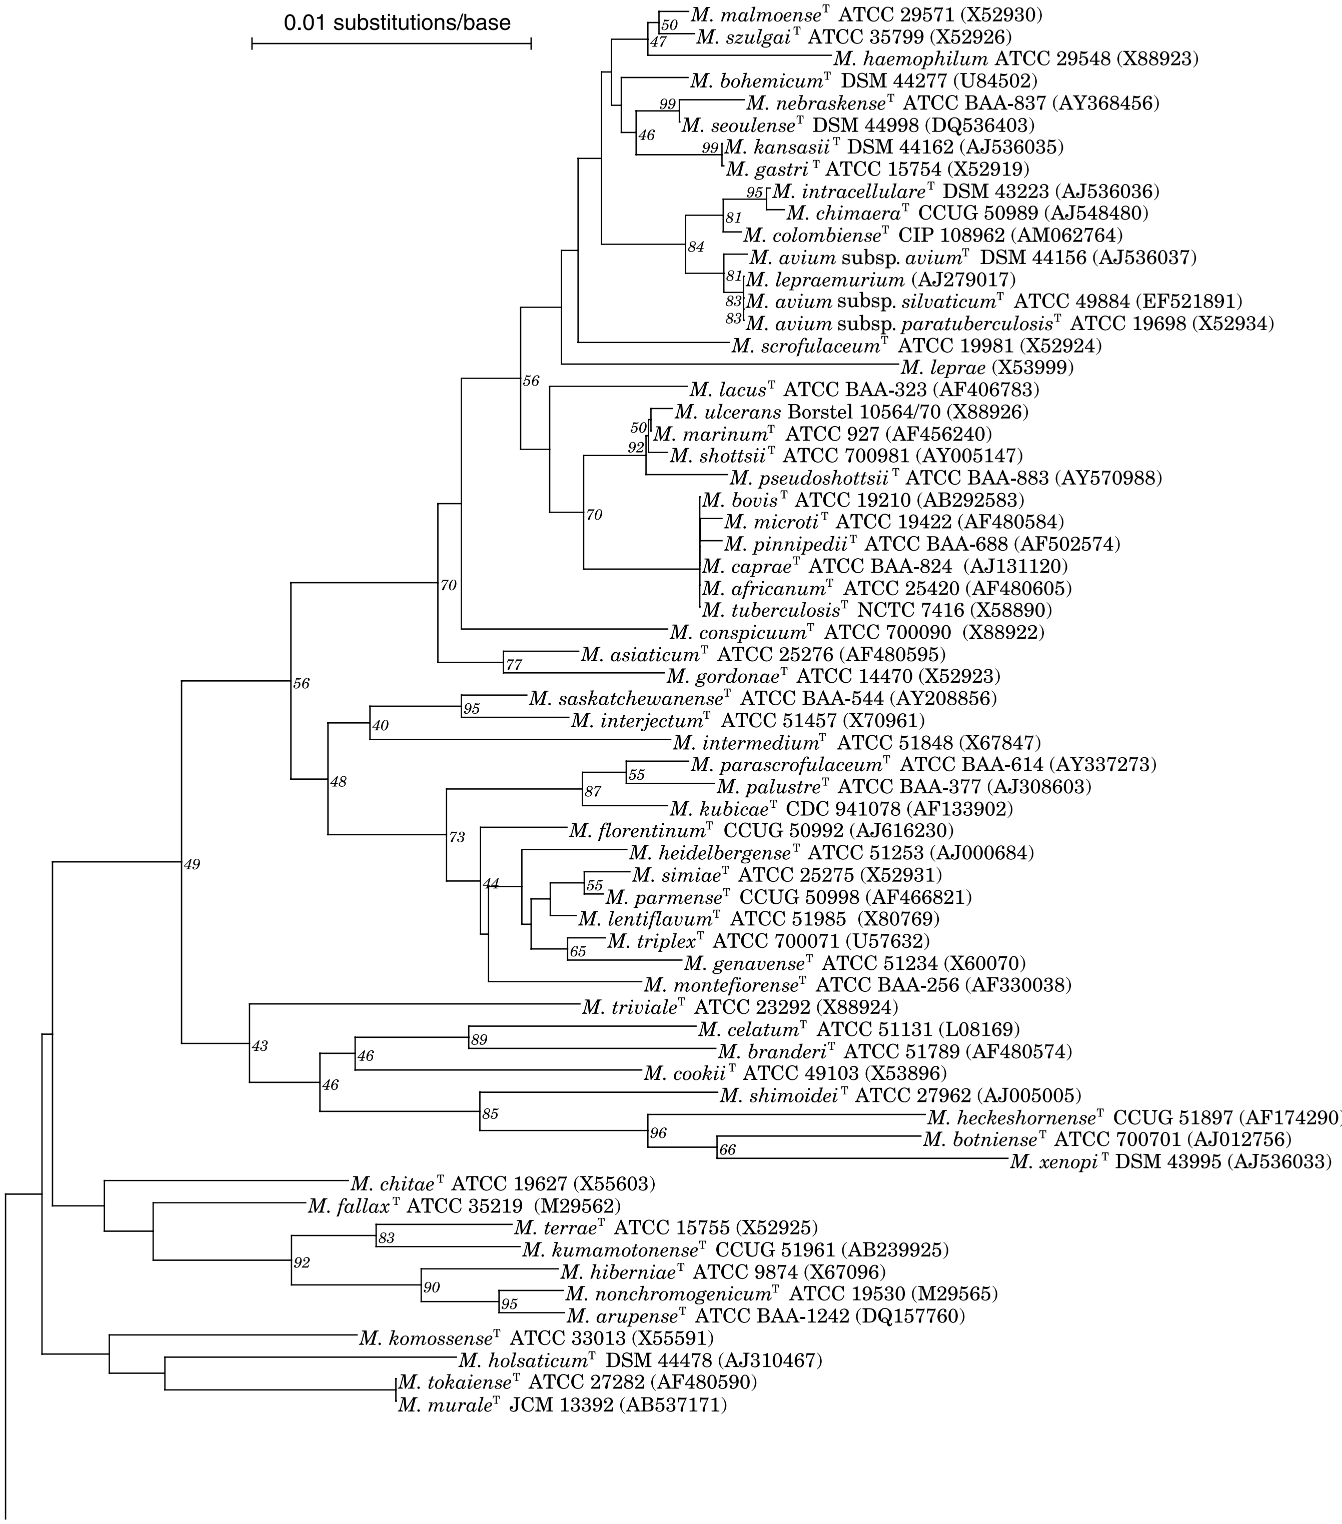

FIGURE 86. Phylogenetic tree generated using Jukes and Cantor (1969) similarities and the neighbor-joining algorithm (Saitou and Nei, 1987) using SEAView v4 (Gouy et al., 2010) and Dendroscope v2.74 (Huson et al., 2007); regions with gaps excluded. Bootstrap values were calculated from 1000 iterations.

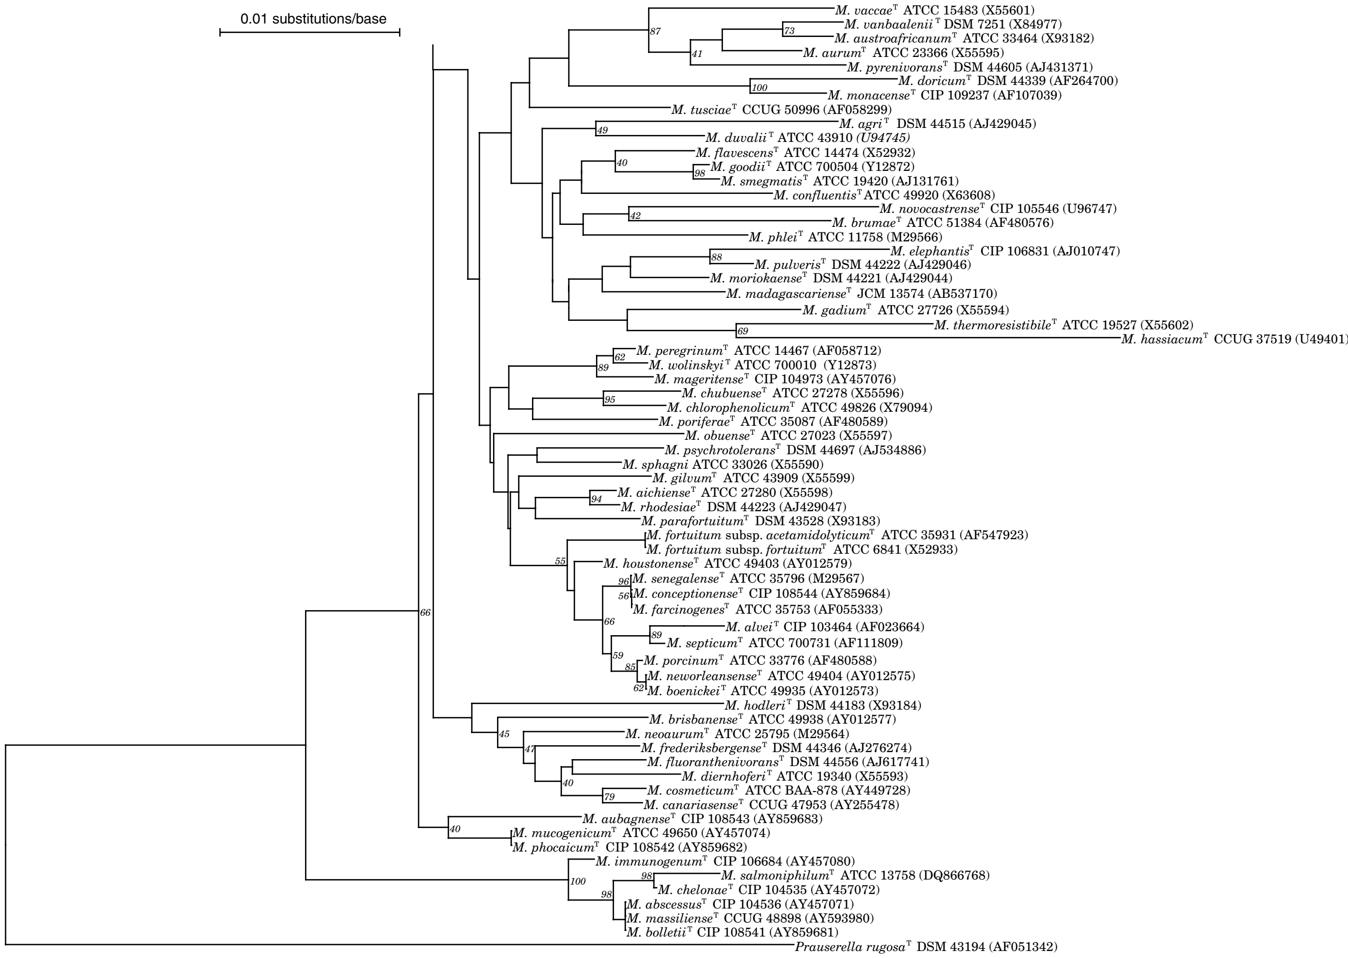

FIGURE 86. (continued)

et al., 1997) and MUSCLE (Edgar, 2004) software and the alignments compared and manually edited taking secondary structure into account by using SEAView v4 (Gouy et al., 2010). Jukes and Cantor (1969) similarities were calculated and phylogenetic trees were generated using the neighbor-joining algorithm (Saitou and Nei, 1987) in SEAView (Gouy et al., 2010); regions with gaps were excluded. Bootstrap values were calculated from 1000 iterations.

Accession numbers for the sequences used in generating the phylogenetic trees are shown in the species descriptions and in Figure 86 and Figure 87 with the exception of those species named above (where type strain sequences are given in the species descriptions but the sequence used is noted in the Figures). A series of phylogenetic trees were generated using different treeing algorithms; a high level of agreement being found between these analyses. 16S rRNA gene sequence data are almost invariably presented as linear dendrograms thereby making it difficult to see detached relationships between species.

The species descriptions which follow are organized into clades based on a consensus of distance (Jukes and Cantor, 1969; Kimura, 1980), parsimony (Fitch, 1977) and maximum likelihood (Felsenstein and Churchill, 1996) trees and phenotypic properties. This allowed the lists of phenotypic characters in Table 37 and Table 38 to be displayed in related groups.

Acknowledgements

A great debt is due to Laurence G. Wayne and George P. Kubica for their classification of the family *Mycobacteriaceae* in the last edition of *Bergey's Manual*. It is testimony to their expertise and forethought that many aspects of their work have survived in the current treatment of the genus.

List of slow-growing species of the genus *Mycobacterium*

Multimembered 16S rRNA gene clades

The *Mycobacterium tuberculosis* clade

1. **Mycobacterium tuberculosis** (Zopf 1883) Lehmann and Neumann 1896, 363[AL] (*Bacterium tuberculosis* Zopf 1883, 67)

tu.ber.cu.lo′sis. L. dim. n. *tuberculum* a small swelling, tubercle; Gr. suff. *-osis* suffix expressing state or condition, in medical terminology denoting a state of disease; N.L. gen. n. *tuberculosis* of tuberculosis.

Strongly acid–alcohol-fast rods (0.3–0.6 × 1–4 μm), straight or slightly curved, occurring singly and in occasional threads. Staining may be uniform or irregular, often showing banded or beaded forms. On most solid media, colonies are rough, raised, and thick, with a nodular or wrinkled surface and an irregular thin margin; may become somewhat pigmented (off-white to faint buff, or even yellow). Growth tends to be in serpentine, cordlike masses in which the bacilli show a parallel orientation. Colonies of avirulent forms are less compact. Colonies on oleic acid-albumin agar are flat, rough, corded, dry, and usually non-pigmented. In liquid media lacking a dispersing agent, strains form a pellicle which, with age, becomes thick and wrinkled. In Dubos' Tween albumin medium, growth is diffuse, settling if undisturbed, but readily dispersed. Generation time *in vitro* under optimal conditions is 14–15 h.

The optimal temperature for growth is 37°C some growth occurs at 30–34°C. Optimum pH is 6.4–7.0. Growth is stimulated by incubation in air with 5–10% added CO_2, and by inclusion of glycerol [0.5% (w/v)] in the medium. Bacilli grown under highly aerobic conditions die rapidly on abrupt shift to anaerobiosis, but when allowed to grow and settle slowly through a self-generated oxygen gradient they adapt a tolerance to oxygen deprivation and exhibit synchronized growth on resuspension (Wayne and Lin, 1982). TLC of methanolysates shows α-, keto-, and methoxy-mycolates. The Differential characteristics of slowly growing species are shown in Table 37.

Strain-to-strain differences in tubercle bacilli have been demonstrated by their different phage susceptibility patterns, but three major patterns are recognized (Bates and Mitchison, 1969; Rado et al., 1975). In cross-sensitivity studies using experimentally sensitized animals, extracts (sensitins) of *Mycobacterium tuberculosis* cannot be differentiated from those of *Mycobacterium africanum*, *Mycobacterium bovis*, or *Mycobacterium microti*, although they are readily distinguished from those of other species (Magnusson, 1980). Similarly, immunodiffusion analysis of bacillary extracts shows a pattern common to *Mycobacterium africanum*, *Mycobacterium bovis*, *Mycobacterium microti*, and *Mycobacterium tuberculosis* (Stanford and Grange, 1974). Monoclonal antibodies have been prepared that appear to distinguish between *Mycobacterium bovis* and *Mycobacterium tuberculosis*, although the specificity of at least one such preparation appears to be at the strain rather than the species level (Coates et al., 1981; Daniel and Janicki, 1978). Immunological analysis of T-catalase extracted from *Mycobacterium tuberculosis* indicates structural identity with that of *Mycobacterium africanum* and *Mycobacterium bovis* and marked divergence from that of other *Mycobacterium* species (Wayne and Diaz, 1979).

Infected animals, including man, exhibit delayed hypersensitivity to crude or purified *Mycobacterium tuberculosis* culture filtrates (tuberculins) and less sensitivity to tuberculin-like preparations from other mycobacteria. Disease caused by *Mycobacterium bovis* cannot be distinguished from that due to *Mycobacterium tuberculosis* by use of commonly available tuberculins. Infections by other mycobacterial species result in much lower degrees of sensitivity to tuberculin, although if "second strength" (250 tuberculin units) PPD tuberculin is used, skin tests may be interpreted erroneously as indicating *Mycobacterium tuberculosis.* Discovery of the role of T-lymphocytes and interferon-gamma in the immune system offered an alternative to tuberculin skin tests (TSTs; Rothel et al., 1990) and led to the development of assays for cell-mediated immune reactivity (Lalvani et al., 2001; Mazurek et al., 2001). By using artificially produced *Mycobacterium tuberculosis*-specific antigens, notably ESAT-6 (early secretory antigen target-6) and CFP-10 (culture filtrate protein-10), which are present in PPD but absent from the BCG strain and from most non-tuberculous mycobacteria, cross-reactivity is largely eliminated and assays correlate with high specificity to *Mycobacterium tuberculosis* exposure (Ewer et al., 2003; Mori et al., 2004).

Experimentally, from an inoculum of 0.01 mg, *Mycobacterium tuberculosis* is highly pathogenic for guinea pigs and hamsters, but relatively non-pathogenic for bovines, cats, domestic fowls, goats, and rabbits. Inocula of 0.001–1 mg produce experimental disease in mice. Attenuation of virulence may occur spontaneously upon subculture in artificial media. Virulence can be maintained by selection of appropriate portions of growth in suitable media or by animal passage. Strains of *Mycobacterium tuberculosis* isolated from patients from southern India may cause only localized lesions in guinea pigs and these tend to regress. These strains produce catalase and are susceptible to both hydrogen peroxide and isoniazid (Mitchinson et al., 1960). Resistance to isoniazid is frequently accompanied by changes in other properties, such as loss of peroxidase and catalase activity and attenuation of virulence for guinea pigs (Middlebrook, 1954; Middlebrook and Cohn, 1953).

Source: isolated from cases of tuberculosis in man, other primates, dogs and some other animals which have contact with man.

DNA G+C content (mol%): 65.6 (whole-genome sequencing).

Type strain: ATCC 27294.

Sequence accession no. (16S rRNA gene): X58890.

Additional remarks: phenotypic distinctions can be made between *Mycobacterium tuberculosis* and *Mycobacterium africanum*, *Mycobacterium bovis*, and *Mycobacterium microti*, but numerical taxonomic data places them all in a "macro cluster", distinct from other slowly growing mycobacteria. DNA–DNA homology between *Mycobacterium bovis* and *Mycobacterium tuberculosis* is about 100% (Baess, 1979). All members of the *Mycobacterium tuberculosis* complex share identical 16S rRNA and ITS sequences. However, *gyrB* polymorphism analysis can help to separate some species (Kasai et al., 2000).

2. **Mycobacterium africanum** Castets, Rist and Boisvert 1969, 321[AL]

a.fri.ca′num. L. neut. adj. *africanum* of Africa, African.

Rods averaging 3 μm in length. Colonies are flat, dull, and rough when grown on egg medium at 37°C. Sodium pyruvate stimulates growth in egg medium. Growth is homogeneous in Dubos' medium supplemented with Tween 80 and granular in Youman's medium supplemented with bovine serum. Growth in Lebek agar-deeps occurs 15 mm below the surface. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from sputum of tuberculosis patients in Senegal and a cause of human tuberculosis in tropical Africa.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25420, CIP 105147.

Sequence accession no. (16S rRNA gene): AF480605.

Additional remarks: David et al. (1978) reported that many African strains exhibited more phenotypic heterogeneity than those of *Mycobacterium tuberculosis* and *Mycobacterium bovis* isolated from other geographical areas, but noted that individual *Mycobacterium africanum* strains clustered with one or the other of these species. They also reported that subclustering behavior reflected the geographic region from which they were isolated on the African continent. This observation led to some workers to assign *Mycobacterium africanum* strains to West African subtype I or East African subtype II. The former, which consist of strains isolated from Dakar, Mauritania, and Yaounde, are similar in their phenotypic properties to *Mycobacterium tuberculosis* and the latter, from Burundi and Rwanda, have similar phenotypic features to *Mycobacterium bovis*. Clinical isolates of *Mycobacterium africanum* were found to be indistinguishable from *Mycobacterium bovis* on the basis of pyrolysis MS data (Sisson et al., 1991).

3. **Mycobacterium bovis** Karlson and Lessel 1970, 280[AL]

bo′vis. L. n. *bos* the ox; L. gen. n. *bovis* of the ox.

Short to moderately long acid-fast, Gram-stain-positive, nonmotile rods. On primary isolation, growth is very poor on glycerol-containing media, although repeated subculture permits adaptation to growth on such media. Growth is improved by the addition of pyruvate to media (Stonebrink, 1958). Freshly isolated cultures of *Mycobacterium bovis* are microaerophilic; inocula dispersed into liquid, semisolid, or solid agar media grow within the medium but not on the surface, thereby distinguishing *Mycobacterium bovis* from *Mycobacterium tuberculosis* which is highly aerobic (Schmeidel and Gerloff, 1965). On repeated subculture, *Mycobacterium bovis* will adapt to aerobic growth. Dilute inocula on egg media yield small, rounded, white colonies, with irregular edges and a granular surface after incubation at 37°C for 21 d or more. Colonies on transparent oleic acid-albumin agar are thin, flat, generally corded, and not easily emulsified in the absence of a detergent. Loss of virulence for guinea pigs and rabbits and of catalase activity accompanies a loss of sensitivity to isoniazid, as for *Mycobacterium tuberculosis*. TLC of methanolysates shows a pattern of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Experimentally, highly pathogenic for calves, guinea pigs, and rabbits; at least moderately pathogenic for hamsters and mice; slightly pathogenic for cats, dogs, horses, and rats; not pathogenic for most fowl. Certain strains isolated from cases of lupus and scrofuloderma in man have low pathogenicity for animals (Griffith, 1957).

Source: originally isolated from tubercles in cattle, and generally more pathogenic for animals than *Mycobacterium tuberculosis*. Causes tuberculosis in cattle, both domestic and wild ruminants; in man and other primates; in carnivores including cats and dogs; and in swine, parrots and possibly some birds of prey.

DNA G+C content (mol%): 65.6 (whole-genome sequencing).

Type strain: ATCC 19210, CIP 105234, NCTC 10772.

Sequence accession no. (16S rRNA gene): AB292583.

Additional remarks: All members of the *Mycobacterium tuberculosis* complex share identical 16S rRNA gene and ITS sequences, but *gyrB* polymorphism analysis can aid separation of some species (Kasai et al., 2000). Some differences in phage susceptibility between *Mycobacterium bovis* and *Mycobacterium tuberculosis* have been described (Baess, 1969). *Mycobacterium bovis* has a very close relationship to other species of the *Mycobacterium tuberculosis* complex. The bacillus of Calmette–Guérin (BCG; Calmette and Guérin, 1908) originally conformed to the properties described for *Mycobacterium bovis* apart from much attenuated pathogenicity and anaerobic growth on glycerinated media. However, since its first description, the BCG strain has been maintained and used independently in a number of laboratories throughout the world. Re-examination of some of these isolates showed that they formed a cluster with no greater matching affinity to *Mycobacterium bovis* than to *Mycobacterium tuberculosis* (Wayne et al., 1980). In addition, samples of BCG isolates have been distinguished from *Mycobacterium bovis* and *Mycobacterium tuberculosis* by their mycolic acid patterns (Minnikin et al., 1983). Pyrolysis MS analysis of BCG isolates showed them to be heterogeneous and more closely related to laboratory-adapted strains of *Mycobacterium tuberculosis* than to more recent isolates of either *Mycobacterium bovis* or *Mycobacterium tuberculosis* (Sisson et al., 1991).

4. **Mycobacterium caprae** (Aranaz, Liébana, Gómez-Mampaso, Galán, Cousins, Ortega, Blázquez, Baquero, Mateos, Súarez and Domínguez 1999) Aranaz, Cousins, Mateos and Domínguez 2003, 1788[VP] comb. nov. [*Mycobacterium tuberculosis* subsp. *caprae* Aranaz, Liébana, Gómez-Mampaso, Galán, Cousins, Ortega, Blázquez, Baquero, Mateos, Súarez and Domínguez 1999, 1271; *Mycobacterium bovis* subsp. *caprae* (Aranaz et al. 1999) Niemann, Richter and Rüsch-Gerdes 2002, 435]

ca′pra.e. L. fem. n. *capra* goat; L. fem. gen. n. *caprae* of a goat, the host animal from which the bacterium was first isolated.

Acid–alcohol-fast, asporogenous, nonmotile rods, with weak cord formation. Colonies are smooth and non-chromogenic after incubation at 36°C for 4–6 weeks. Growth is enhanced by pyruvate. Does not grow at 25, 30, or 43°C, or on media supplemented with 5% (w/v) NaCl. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from the lymph nodes and lungs of tuberculous goats and from cattle, deer, pigs, sheep, and wild boars and from a captive Siberian tiger (Aranaz et al., 2003; Aranaz et al., 1999; Erler et al., 2004; Lantos et al., 2003; Prodinger et al., 2002). Has also been found as a pathogen in humans linked with goat farming (Gutierrez et al., 1997).

DNA G+C content (mol%): not determined.

Type strain: CIP 105776, ATCC BAA-824.

Sequence accession no. (16S rRNA gene): AJ131120.

Additional remarks: Mycobacterium caprae was initially described as a subspecies of *Mycobacterium tuberculosis* (Aranaz et al., 1999), and then was transferred to *Mycobacterium bovis* as a subspecies (Niemann et al., 2002). This designation was challenged by Aranaz et al. (2003) who argued that *Mycobacterium caprae* was an evolutionary precursor to *Mycobacterium bovis* (see also Brosch et al., 2002) and, largely on public health grounds, proposed that *Mycobacterium caprae* be elevated to species rank. However, *Mycobacterium caprae* has a very close relationship to other species classified in the *Mycobacterium tuberculosis* complex and has a 16S rRNA gene profile which is characteristic of all members of the *Mycobacterium tuberculosis* complex. It can be separated from *Mycobacterium africanum*, *Mycobacterium bovis*, and *Mycobacterium tuberculosis* strains by spoligotyping (Niemann et al., 2002).

5. **Mycobacterium microti** Reed *in* Breed, Murray and Smith 1957, 703[AL]

mi.cro′ti. N.L. masc. n. *Microtus* a genus that includes the vole; N.L. gen. n. *microti* of *Microtus*.

Acid-fast, Gram-stain-positive, nonmotile rods. Primary growth on glycerol-free egg media in 28–60 d; may adapt to tolerance to glycerol. Colonial morphology is variable. Optimum temperature is 37°C. TLC of methanolysates yields α-, keto-, and methoxy-mycolates. Differential characteristics of the species are shown in Table 37.

Pathogenicity is lost on repeated subculture. The organism is not considered to be a human pathogen, though infections in immune-suppressed individuals have been reported (van Soolingen et al., 1998). Local lesions are produced in calves, rabbits, and guinea pigs. This species causes naturally acquired generalized tuberculosis in voles.

Source: originally isolated from a vole (*Microtus agrestis*) by Wells (1937).

DNA G+C content (mol%): not determined.

Type strain: ATCC 19422, CIP 104256, NCTC 8710.

Sequence accession no. (16S rRNA gene): AF480584.

6. **Mycobacterium pinnipedii** Cousins, Bastida, Cataldi, Quse, Redrobe, Dow, Duignan, Murray, Dupont, Ahmed, Collins, Butler, Dawson, Rodríguez, Loureiro, Romano, Alito, Zumarraga and Bernardelli 2003, 1312[VP]

pin.ni.pe′di.i. N.L. gen. n. *pinnipedii* of a pinniped, referring to the host animal from which the organism was first isolated.

Acid–alcohol-fast, non-spore-forming, nonmotile bacilli which show loose cord formation. Colonies on egg-based medium after incubation for 3–6 weeks are dysgonic, rough, flat, and non-photochromogenic. Growth is generally enhanced by sodium pyruvate. Optimal temperature for growth is 36–37°C. Differential characteristics of slowly growing species are shown in Table 37.

Isolates can be recovered from the lung and associated lymph nodes of tuberculous pinnipeds and occasionally from mesenteric lymph nodes and organs such as the liver. Strains are pathogenic for guinea pigs and rabbits. Incidental infections in bovines, humans, and a tapir suggest the species may have a wide host range and that inter-species transmission is possible (Moser et al., 2008). The ability of this species to cause disease in humans was reported by Thompson et al. (1993).

Source: isolated from captive and wild seals from diverse geographical areas (Cousins et al., 2003).

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-688, NCTC 13288.

Sequence accession no. (16S rRNA gene): AF502574.

Additional remarks: Mycobacterium pinnipedii is closely related to other species classified as *Mycobacterium tuberculosis* complex; it shares a 16S rRNA gene sequence similarity of 99.9% with *Mycobacterium tuberculosis*. Cousins et al. (2003) showed that spoligotypes of *Mycobacterium pinnipedii* formed a distinct and homogeneous cluster within the *Mycobacterium tuberculosis* complex even though strains were from diverse geographical sources. Nevertheless, they recognized four different spoligotypes; all of the isolates from Australia and all but one of those from Argentina had a unique pattern, designated SS1. The pattern of the remaining Argentinian isolate was designated SS2, that of some strains from Great Britain and New Zealand was SS3, and others from New Zealand were SS4.

The *Mycobacterium haemophilum* clade

7. **Mycobacterium haemophilum** Sompolinsky, Lagziel, Naveh and Yankilevitz 1978, 74[AL]

ha.e.mo′phi.lum. Gr. n. *haima* (Latin transliteration *haema*) blood; Gr. adj. *philos* loving; N.L. neut. adj. *haemophilum* blood loving.

Strongly acid–alcohol-fast, short (1.4–3.2 × 0.4–0.7 µm), occasionally curved, nonmotile rods. Non-pigmented, rough colonies appear after incubation for 2–4 weeks on Middlebrook 7H10 agar or Löwenstein–Jensen medium, but only if supplemented with 0.4% hemoglobin or 60 µM hemin, but not with $FeCl_3$ or catalase. Small numbers of smooth colonies often occur. Does not grow on media supplemented with 5% (w/v) NaCl. Dawson and Jennis (1980) report that 15 mg/ml ferric ammonium citrate can be substituted for hemin. Growth is strictly intracellular in tissue culture in fibroblasts (Sompolinsky et al., 1978). Temperature range for growth is 25–35°C and optimal growth is at 30–32°C; does not grow at 37°C. Differential characteristics of slowly growing species are shown in Table 37.

Guinea pigs do not develop any obvious pathology after intravenous, intramuscular, or subcutaneous inoculation with dense suspensions of the organisms. Some mice die 2–4 weeks after inoculation; numerous intracellular bacilli are found in monocytes and macrophages of kidney, liver, and spleen, but gross lesions are not formed.

Source: Isolated in Israel from subcutaneous granulomata of a patient undergoing treatment for Hodgkin's disease. Subsequently found in skin lesions of patients undergoing

immunosuppressive treatment in Australia (Dawson and Jennis, 1980).

DNA G+C content (mol%): not determined.

Type strain: ATCC 29548, CCUG 47452, CIP 105049, DSM 44634, NCTC 11185.

Sequence accession no. (16S rRNA gene): X88923.

Additional remarks: seroagglutination studies of whole bacilli specific for *Mycobacterium haemophilum*, both of Australian and Israeli origin, show little if any cross-reaction with unabsorbed sera and none using absorbed sera, with any of the serovars of *Mycobacterium avium/Mycobacterium intracellulare* complex or *Mycobacterium asiaticum*, *Mycobacterium malmoense*, *Mycobacterium marinum*, *Mycobacterium scrofulaceum*, *Mycobacterium simiae*, *Mycobacterium szulgai*, or *Mycobacterium ulcerans* (Dawson and Jennis, 1980; Sompolinsky et al., 1978).

8. **Mycobacterium malmoense** Schröder and Juhlin 1977, 245[AL]

mal.mo.en′se. N.L. neut. adj. *malmoense* of or belonging to Malmö, Sweden, the source of the strains on which the original description is based.

Acid–alcohol-fast, Gram-stain-positive, coccoid to short rods are formed on Löwenstein–Jensen medium; longer rods occur when grown on Middlebrook 7H10 agar. Neither cording nor cross-barring occurs. Cells are non-capsulate and asporogenous. Does not produce aerial hyphae. Colonies are smooth, grayish white, non-pigmented, usually domed, and circular. Some umbonate colonies occur with compact, raised centers and flattened irregular edges on Middlebrook and cornmeal agars. Growth requires incubation for over 1 week and may take up to 6 weeks. Temperature range for growth is 22–37°C; growth does not occur at 42°C. Strains are micro-aerophilic and grow beneath the surface of semi-solid agar medium after deep inoculation. TLC of methanolysates shows the presence of α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Subcutaneous inoculation of guinea pigs with 0.1 mg bacilli produces local, but not generalized, lesions. Intravenous inoculation of chickens with 0.1 mg bacilli caused macroscopic lesions in the liver and spleen in about half of the birds, some of which died. Intravenous inoculation of rabbits with 0.1 mg bacilli caused rare minimal lesions that contained rare viable bacilli.

Source: isolated from sputum and biopsy specimens from patients with pulmonary disease and considered to be the etiologic agent of the disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 29571, CCUG 37761, CIP 105775, DSM 44163, JCM 13391, NCTC 11298.

Sequence accession no. (16S rRNA gene): X52930.

Additional remarks: seroagglutination studies have demonstrated the presence of a single serovar in *Mycobacterium malmoense* that is distinct from those of other *Mycobacterium* species. Similarly, strains exhibit a single unique TLC pattern of surface lipids (Wayne et al., 1983), while dermal hypersensitivity studies show distinction from other *Mycobacterium* species (Schröder and Juhlin, 1977). In numerical taxonomy studies, Wayne et al. (1983) demonstrated that *Mycobacterium malmoense* formed a discrete cluster with 85% internal matching similarity, but with corresponding low similarities to other mycobacterial clusters.

9. **Mycobacterium bohemicum** Reischl, Emler, Horak, Kaustova, Kroppenstedt, Lehn and Naumann 1998, 1354[VP]

bo.he′mi.cum. N.L. neut. adj. *bohemicum* referring to the Czech Republic where the organism was first isolated.

Acid-fast, rod-shaped cells. Smooth, scotochromogenic colonies that are 1–2 mm in diameter are formed on Löwenstein–Jensen medium and Middlebrook 12B agar following incubation for 4–6 weeks. Does not grow on media containing 5% (w/v) NaCl. Temperature range for growth is 25–40°C; optimal growth temperature is 37°C; does not grow at 42 or 45°C. TLC of methanolysates shows the presence of α-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: originally isolated from three consecutive sputum samples from a patient with Down's syndrome suffering from tuberculosis. Subsequently, the species has been considered to be a cause of lymphadenitis in immunocompetent children (Tortoli et al., 2000) and has been isolated from veterinary and environmental sources (Torkko et al., 2001).

DNA G+C content (mol%): 63.5 (HPLC).

Type strain: DSM 44277, JCM 12402, CIP 105808/105811.

Sequence accession no. (16S rRNA gene): U84502.

The *Mycobacterium kansasii* clade

10. **Mycobacterium kansasii** Hauduroy 1955, 73[AL]

kan.sas′i.i. N.L. gen. n. *kansasii* of Kansas, USA.

Moderately long to long acid-fast rods which broaden and exhibit cross-barring when grown in the presence of fatty acids. Dilute inocula on agar or inspissated egg media yield smooth to rough colonies after incubation at 37°C for 7 or more days. Colonies usually appear somewhat rough microscopically, but are readily emulsified in water; some strains resist emulsification. Colonies grown in the dark are non-pigmented; when grown in light, or when exposed briefly to light young colonies become brilliant yellow (photochromogenic). Rarely, strains produce a deep orange pigment when grown in the dark or do not form pigments. Most strains, when grown in a lighted incubator, form dark red crystals of β-carotene on the surface and inside colonies (Runyon, 1965). Temperature range for growth is 32–42°C; does not grow at 45°C. TLC of methanolysates shows α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Causes chronic human pulmonary disease resembling tuberculosis although not normally considered contagious from man to man (Wolinsky, 1979a). Pathogenicity may be related to catalase activity; isolates with strong catalase activity are thought to be more virulent (Steadham, 1980). Most strains are strongly catalase-positive, but some are weakly positive and inactivated at 68°C for 20 min, i.e. lacking M-catalase (Wayne and Diaz, 1982); these variants appear to be less pathogenic for man (Wayne, 1962).

Source: isolated from human pulmonary lesions. Occasionally associated with lesions of lungs or lymph nodes of cattle, deer, and swine (Pattyn et al., 1967; Worthington and Kleeberg, 1964). Extensive soil sampling has failed to yield isolates of *Mycobacterium kansasii* (Wolinsky and Rynearson, 1968), but strains have been isolated from domestic water sources (Bailey et al., 1970; Engel et al., 1980; Fisheder

et al., 1991; Kaustova et al., 1981; Steadham, 1980) suggesting that the organism may be concentrated within water distribution systems. *Mycobacterium kansasii* is one of several species frequently incriminated in nosocomial and pseudo-outbreaks (Phillips and von Reyn, 2001).

DNA G+C content (mol%): not determined.

Type strain: ATCC 12478, CIP 104589, DSM 44162, JCM 6379, NCTC 13024.

Sequence accession no. (16S rRNA gene): AJ536035.

Additional remarks: Magnusson (1967) distinguished between *Mycobacterium kansasii* and 10 other *Mycobacterium* species, including *Mycobacterium marinum*, by dermal hypersensitivity testing. Dermal desensitization is effected only by homologous antigens although some degree of cross-reactivity does occur (Worthington and Kleeberg, 1967). One agglutinating serovar characteristic of *Mycobacterium kansasii* was used to identify 154 out of 155 tested smooth strains, the identities of which were confirmed by biochemical means (Hobby et al., 1967). It was not possible to type rough strains due to spontaneous agglutination. High and low catalase variants exhibit the same agglutinating serovar (Wayne, 1966). Cross-reactivity does not occur between the surface antigens of *Mycobacterium kansasii*, *Mycobacterium gastri*, and *Mycobacterium marinum* (Wayne et al., 1978). Immunodiffusion analysis of cell extracts of *Mycobacterium kansasii* showed four antigens that were not shared with other mycobacterial species with the exception of *Mycobacterium gastri* (Stanford and Grange, 1974). The T-catalase of *Mycobacterium gastri* shows a very close structural relationship to that of *Mycobacterium kansasii* (Wayne and Diaz, 1982).

11. **Mycobacterium gastri** Wayne 1962, 923[AL]

gas′tri. L. n. *gaster -tri* belly, stomach; L. gen. n. *gastri* of the stomach.

Acid–alcohol-fast moderately long rods which frequently show cross-barring. Smooth to rough and pale buff to white colonies are formed on inspissated egg medium. On oleic acid-albumin agar, smooth or somewhat granular colonies are formed after incubation at 37°C for 7 or more days. Temperature range for growth is 25–40°C.

Closely related to *Mycobacterium kansasii* biochemically, but is not agglutinated by *Mycobacterium kansasii*-typing serum (Wayne, 1966) nor does the phenol-soluble antigen cross-react with this serum (Wayne, 1971). Immunodiffusion of cell extracts or culture filtrates does not permit differentiation between *Mycobacterium gastri* and *Mycobacterium kansasii* (Norlin et al., 1969; Stanford and Grange, 1974). Similarly, serological analysis of T-catalases does not demonstrate any significant difference between *Mycobacterium gastri* and *Mycobacterium kansasii*; only strains of the latter produce an M-catalase (Wayne and Diaz, 1982). *Mycobacterium gastri* forms a homogeneous group by reciprocal intradermal skin testing and is thereby distinguishable from *Mycobacterium kansasii* (Magnusson, 1971). TLC of methanolysates shows the presence of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Fails to produce progressive disease in guinea pigs, but is usually capable of producing local ulceration at sites with intradermal inoculation of 10^2–10^3 mg bacilli (Wayne, 1966).

Source: isolated from a specimen of human gastric lavage. Found in human gastric lavage or sputum specimens as casual residents, but is not considered to be a cause of disease (Kestle et al., 1967; Wayne, 1966). Also found in soil (Wolinsky and Rynearson, 1968).

DNA G+C content (mol%): not determined.

Type strain: ATCC 15754, CCUG 20995, CIP 104530, DSM 43505, JCM 12407.

Sequence accession no. (16S rRNA gene): X52919.

Additional remarks: in the 1st (1986) edition of *Bergey's Manual of Systematic Bacteriology*, Wayne and Kubica noted that "the similarities of cytoplasmic antigens of *Mycobacterium gastri* to those of *Mycobacterium kansasii*, as well as a number of shared biochemical properties, raised the question of whether *Mycobacterium gastri* represents a distinctly separate species. The distinctions based on M-catalase, nitrate reduction, pigment, drug susceptibility, surface antigens and clinical significance have tended to support separation of the species. However, the 16S rRNA gene phylogeny does not distinguish between these two species." Further studies are needed.

12. **Mycobacterium nebraskense** Mohamed, Iwen, Tarantolo and Hinrichs 2004, 2060[VP]

ne.bras.ken′se. N.L. neut. adj. *nebraskense* of or belonging to the State of Nebraska, USA.

Acid-fast, non-sporing rods. Growth occurs in 3 weeks on Middlebrook 7H11 agar and in 4 or more weeks on Löwenstein–Jensen medium. Colonies are rough with an elevated center and produce strong yellow pigmentation in the dark. Growth is inhibited on MacConkey agar (without crystal violet) and on 5% (w/v) NaCl agar. Temperature range for growth is 25–35°C; optimal temperature is 30–35°C; does not grow at 42°C. Differential characteristics of slowly growing species are shown in Table 37.

Source: description of this organism is based on five strains isolated from the sputum of patients living in different areas of Nebraska.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-837, DSM 44803.

Sequence accession no. (16S rRNA gene): AY368456.

The *Mycobacterium avium* clade

13. **Mycobacterium avium** Chester 1901, 356[AL]

13a. **Mycobacterium avium subsp. avium** Chester 1901, 356[AL] (nom. cons. Opin. 47, Jud. Comm. 1973) Thorel, Krichevsky and Lévy-Frébault 1990, 258[VP]

a′vi.um. L. n. *avis* a bird; L. gen. pl. n. *avium* of birds.

Cells are short to long rods with some filaments, but no evidence of cord formation. Dilute inocula on inspissated egg or oleic acid-albumin media usually yield smooth, but occasionally rough, non-pigmented colonies after 7 or more days of incubation at 37°C; on ageing, colonies may become yellow. Temperature range for growth is 37–42°C; human/porcine isolates may have an extended temperature range (25–45°C). Some strains may be scotochromogenic exhibiting a bright yellow pigment (Thorel et al., 1990). Certain strains are tolerant of 5% (w/v) NaCl when incorporated in Middlebrook 7H10 medium. When

first isolated from lesions, colonies on agar are flat and translucent, and exhibit the characteristic pathogenicity in experimental animals described below. On repeated passage, this colony form is replaced by a domed opaque type; the latter shows greatly diminished pathogenicity (Meissner et al., 1974).

Schaefer (1965) established two agglutinating serovars for *Mycobacterium avium*. Bacilli isolated from diseased birds almost always fall into one of these serovars, with serovar II as the most frequent cause of natural bird infection. Subsequently, Marks et al. (1969) showed that serovar II could be divided into two subtypes which showed some cross-reaction. The serovar designations I and II have since been replaced by serovars 1, 2, and 3 (Wolinsky and Schaefer, 1973). Serovar 2 is the most consistently pathogenic in experimental infection of chickens. Stanford and Grange (1974) found that, in addition to common genus antigens, immunodiffusion analysis of extracts revealed at least six antigens which were shared by *Mycobacterium avium*, *Mycobacterium intracellulare*, and *Mycobacterium lepraemurium*, but not by other mycobacterial species. Reciprocal intradermal testing in most cases permits discrimination between *Mycobacterium avium* and *Mycobacterium intracellulare* (Magnusson, 1980; Meissner et al., 1974). Strains of *Mycobacterium avium* may be susceptible to several phages, but no pattern is characteristic of any given serovar (Crawford et al., 1981b). TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Avian serovars 1 and 2 are widely distributed over at least three continents (Wolinsky and Rynearson, 1968), although type 3 is seen mainly in Europe (Marks et al., 1969). Experimentally, in the rabbit and mouse, the organism usually proliferates without macroscopic tubercles. Not pathogenic for guinea pigs or rats. Lesions in cattle may be caused by either *Mycobacterium avium* or *Mycobacterium intracellulare* serovars (Schaefer, 1968). Chickens infected intravenously with 5 mg moist bacilli die within 2 months, showing gross lesions in the spleen and microscopic lesions in lungs and spleen (Engbaek et al., 1968). An inoculum of 0.01 mg kills rabbits, but not mice. Rabbits inoculated intravenously with 5 mg moist bacilli usually die within 40 d showing macroscopic lesions in the spleen, and occasionally lungs, and microscopic lesions in the spleen and lungs. Animals surviving 3 months show lesions in joints and tendon sheaths (Engbaek et al., 1964; Engbaek et al., 1968).

Mycobacterium avium serotypes have been implicated in human pulmonary disease, although *Mycobacterium avium*-like organisms causing human disease are usually more similar to *Mycobacterium intracellulare* and fit one of the serovars of that species (Hobby et al., 1967). *Mycobacterium avium* may cause disseminated disease in immunocompromised individuals and lymphadenitis in immunecompetent children (Thorel et al., 1990). Other properties of the organisms can be found elsewhere (Thorel et al., 1990; Wayne and Kubica, 1986).

Source: isolated from tubercles in fowls. Widely distributed as the causal agent of tuberculosis in birds and less frequently found in lesions or lymph nodes of cattle, swine, or other animals. Rarely found in soil.

DNA G+C content (mol%): 69.0 (whole-genome sequencing).

Type strain: ATCC 25291, CCUG 20992, CIP 104244, DSM 44156, NCTC 13034.

Sequence accession no. (16S rRNA gene): AJ536037.

Additional remarks: the subspecies name *Mycobacterium avium* subsp. *avium* Chester 1901 was automatically created by the valid publications of *Mycobacterium avium* subsp. *paratuberculosis* (Bergey et al. 1923; Thorel et al. 1990), and of *Mycobacterium avium* subsp. *silvaticum* Thorel et al. 1990. Separation of *Mycobacterium avium* into three subspecies is supported by numerical taxonomic data (Thorel et al., 1990) and by analysis of DNA fragments by field inversion gel electrophoresis (Lévy-Frébault et al., 1989). Based on differences in *IS*1245 RFLP, the 16S–23S rRNA gene ITS sequences, and growth temperature, it has been suggested, but not formally proposed, that the designation *Mycobacterium avium* subsp. *avium* be reserved for bird-type isolates and that of "*Mycobacterium avium* subsp. *hominissuis*" be applied to strains isolated from humans or pigs (Mijs et al., 2002).

In cooperative taxonomy studies based on biochemical tests, growth characteristics, and drug susceptibilities, *Mycobacterium avium* and *Mycobacterium intracellulare* present as clusters with extensive overlap, whereas *Mycobacterium scrofulaceum* appears as a discrete cluster (Meissner et al., 1974; Wayne, 1982). Hawkins (1977) proposed that strains which appear to belong to *Mycobacterium avium*, *Mycobacterium intracellulare*, or *Mycobacterium scrofulaceum*, but are inconsistent in phenotypic properties, be treated as *Mycobacterium avium/intracellulare/scrofulaceum* (MAIS) intermediates until their taxonomic standing could be clarified. This proposal has been misinterpreted by some workers who refer to the "MAIS complex", a taxon which includes well-defined strains of these three species, implying that they bear a close taxonomic relationship to one another. There is ample evidence, based on numerical taxonomic data (Meissner et al., 1974), reciprocal intradermal skin testing (Magnusson, 1980), immunodiffusion studies (Stanford and Grange, 1974), immunologic distance of catalases (Wayne and Diaz, 1979, 1982), and DNA homology data (Baess, 1979), that *Mycobacterium scrofulaceum* is distinct from *Mycobacterium avium* and *Mycobacterium intracellulare*. These studies provide more equivocal evidence on relationships between *Mycobacterium avium* and *Mycobacterium intracellulare*, as reflected in two conflicting recommendations, presented as majority and minority opinions, on the advisability of reducing *Mycobacterium intracellulare* to synonymy of *Mycobacterium avium* (Meissner et al., 1974). DNA–DNA hybridization studies have confirmed that *Mycobacterium avium*, *Mycobacterium intracellulare*, and *Mycobacterium scrofulaceum* belong to distinct genomic species and indicate that strains belonging to serovars 4, 5, 6, and 8 appear to be more closely related to *Mycobacterium avium* than to *Mycobacterium intracellulare* (Baess, 1983). For convenience in clinical mycobacteriology, strains phenotypically resembling *Mycobacterium avium* (including *Mycobacterium intracellulare*) and not distinguished by molecular hybridization probes are said to belong to the *Mycobacterium avium* complex (MAC). Several strains formerly assigned to this complex have now been described as separate species.

13b. **Mycobacterium avium subsp. paratuberculosis** (Bergey et al. 1923) Thorel, Krichevsky and Lévy-Frébault 1990, 259[VP] (*Mycobacterium paratuberculosis* Bergey, Harrison, Breed, Hammer and Huntoon 1923, 374)

pa.ra.tu.ber.cu.lo′sis. Gr. pref. *para* beside, related; N.L. n. *tuberculosis* tuberculosis; N.L. gen. n. *paratuberculosis* of tuberculosis-like, of paratuberculosis.

Cells are cocco-bacillary, 1–2 μm in length. They stain uniformly, but occasionally longer forms may show alternately stained and unstained segments. Cord formation does not occur. This organism is difficult to cultivate. Originally, growth in primary cultures was only possible in media containing heat-killed acid-fast bacilli (Twort and Ingram, 1913). It is now apparent that this requirement can be overcome by supplementing media with mycobactin (Snow, 1970). Mycobactins are iron-binding hydroxamate compounds produced by all mycobacteria, except *Mycobacterium avium* subsp. *paratuberculosis*. On subculture strains can be adapted to produce a mycobactin (Merkal and McCullough, 1982). Growth may be further stimulated by pyruvate, but is not enhanced by culture at pH 5.5 (Thorel et al., 1990). Growth is inhibited by 5% (w/v) NaCl. Strains are characteristically tolerant to cycloserine (50 μg/ml). Despite the presence of growth stimulants, 3–4 months are necessary for primary isolation. On subculture, rough, non-pigmented colonies appear after incubation for 3–6 weeks. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from cattle with chronic hypertrophic enteritis or Johne's disease by Johne and Frothingham (1895). The organism also causes enteritis in other ruminants and has been implicated in the pathogenesis of Crohn's disease in humans (McFadden et al., 1992; McFadden et al., 1987). Strains have not been isolated from the environment.

DNA G+C content (mol%): 69.3 (whole-genome sequencing).

Type strain: ATCC 19698, CIP 103963, DSM 44133.

Sequence accession no. (16S rRNA gene): X52934.

Additional remarks: Mycobacterium avium subsp. *paratuberculosis* can be distinguished from other members of the MAC by its stable mycobactin dependence (Thorel et al., 1990) and by the presence of multiple copies of the unique insertion element *IS*900 (Green et al., 1989; McFadden et al., 1992; McFadden et al., 1987). Three RFLP types have been recognized in animal isolates of the organism using an *IS*900 probe. Bovine and ovine strains shared the same RFLP types (types A and B), whereas a single caprine isolate had a unique RFLP pattern (type C).

13c. **Mycobacterium avium subsp. silvaticum** Thorel, Krichevsky and Lévy-Frébault 1990, 259[VP]

sil.va′ti.cum. L. neut. adj. *silvaticum* of or belonging to a wood or to trees.

Acid-fast short to long rods with no cord formation. Rough colonies occur after incubation for 2 weeks or more on oleic acid medium when enhanced by low pH (pH 5.5). Growth is not stimulated by pyruvate and does not occur on Löwenstein–Jensen or other egg-based media. Growth is inhibited by 5% (w/v) NaCl and by cycloserine (50 μg/ml). Strains do not require mycobactin for growth. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from birds, especially wood pigeons and cranes, and from mammals, especially deer. Strains have not been isolated from the environment and are obligate pathogens for animals, causing tuberculosis in birds and paratuberculosis in mammals (Collins et al., 1985; Mathews and McDiarmid, 1979; McDiarmid, 1948).

DNA G+C content (mol%): not determined.

Type strain: CIP 103317, ATCC 49884, CCUG 47446, DSM 44175.

Sequence accession no. (16S rRNA gene): EF521891.

14. **Mycobacterium intracellulare** (Cuttino and McCabe 1949) Runyon 1965, 258[AL] [*Nocardia intracellularis* Cuttino and McCabe 1949, 16; *Mycobacterium intracellularis* (*sic*) Runyon 1965, 258]

in.tra.cel.lu′la.re. L. prep. *intra* within; L. n. *cellula* small room and in biology a cell; L. neut. suff. *-are* suffix denoting pertaining to; N.L. neut. adj. *intracellulare* intracellular.

Acid-fast, short to long rods; transiently filamentous in new growth, eventually becoming coccobacillary. Dilute inocula on inspissated egg and oleic acid agar media usually yield smooth, rarely rough, non-pigmented colonies after incubation at 37°C for 7 or more days; on ageing, colonies may become yellow. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from fatal systemic disease in a child. Most frequently encountered in pulmonary secretions from individuals suffering from tuberculosis-like disease and from surgical specimens of such patients. When isolated from human secretions, it often represents the etiologic agent of pulmonary disease, although it is frequently isolated as an apparent casual resident (Wolinsky, 1979a). Also isolated from limited disease processes in cattle and swine. Occasionally found in soil or water (Wendt et al., 1980; Wolinsky and Rynearson, 1968).

DNA G+C content (mol%): not determined.

Type strain: ATCC 13950, CCUG 28005, CIP 104243, DSM 43223, JCM 6384, NCTC 13025.

Sequence accession no. (16S rRNA gene): AJ536036.

Additional remarks: Experimentally, causes limited disease in chickens and mice though much less severe than *Mycobacterium avium*, and rarely fatal. In general, chicken pathogenicity corresponds to serovar, with *Mycobacterium avium* serovar II more consistently pathogenic than the *Mycobacterium intracellulare* serovars (Meissner et al., 1974). Growth at 42°C has been reported to increase pathogenicity (Scammon et al., 1964). Lesions in guinea pigs are usually limited to the site of inoculation. Hamsters inoculated intra-testicularly show extensive local lesions and, frequently, secondary focal lesions in liver, spleen, and abdominal lymph nodes. Rabbits receiving 10^{-3} mg intravenously do not develop demonstrable lesions (Feldman and Ritts, 1963) but 5 mg, although not causing death,

produces rare macroscopic lesions in visceral organs and usually moderate-to-severe lesions in joints and tendon sheaths (Engbaek et al., 1964).

At least 17 agglutinating serovars have been established among cultures identified as *Mycobacterium intracellulare* (Wolinsky and Schaefer, 1973), but have been labeled "*avium* complex" (serovars 4–20). Members of these serovars are predominantly non-pathogenic for chickens and have been isolated mainly from man, cattle, and swine, as opposed to three distinct serovars of *Mycobacterium avium*, which are virulent for chickens, and less frequently associated with mammalian disease. Strains of "*avium* complex" serovar 8, once proposed as the separate species "*Mycobacterium brunense*" (Kazda, 1967) and later considered to belong to *Mycobacterium intracellulare* (Kubin et al., 1969) appear intermediate between *Mycobacterium avium* and *Mycobacterium intracellulare* in virulence for experimental animals. Many, if not most strains of "*avium* complex" serovar 18 more closely resemble *Mycobacterium simiae* than *Mycobacterium intracellulare* (Wayne et al., 1983). No single phage typing pattern is characteristic of this species or of individual serovars within it (Crawford et al., 1981b). See also discussion of the antigenic structure of *Mycobacterium avium*.

15. **Mycobacterium chimaera** Tortoli, Rindi, Garcia, Chiaradonna, Dei, Garzelli, Kroppenstedt, Lari, Mattei, Mariottini, Mazzarelli, Murcia, Nanetti, Piccoli and Scarparo 2004, 1283[VP]

chi.ma.e′ra. L. fem. n. *chimaera* the chimaera, the mythological being composed of parts of three different animals, referring to the apparent mix of genetic features characterizing the strains.

Acid-fast, nonmotile, non-spore-forming cocco-bacilli. Colonies are slow-growing and non-pigmented. Growth does not occur on MacConkey agar or on media supplemented with 5% (w/v) NaCl. Temperature range for growth is 25–37°C; does not grow at 45°C. In the widely used Accuprobe identification system, *Mycobacterium chimaera* strains hybridize with probes for the *Mycobacterium avium* complex and for *Mycobacterium intracellulare*, but not with the specific probe for *Mycobacterium avium*. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from either sputum or bronchial aspirates obtained from elderly patients. Seven of the twelve strains studied by Tortoli et al. (2004) were considered to be of clinical significance.

DNA G+C content (mol%): not determined.

Type strain: CIP 107892, CCUG 50989, DSM 44623.

Sequence accession no. (16S rRNA gene): AJ548480.

Additional remarks: the 16S rRNA gene sequence of this species shows only one nucleotide mismatch with that of *Mycobacterium intracellulare* compared with 20 or more mismatches in sequences in the 16S–23S rRNA gene-ITS region. In contrast, the ITS sequence showed only one mismatch in comparison to that of sequevar *Mycobacterium avium* complex-A. However, *Mycobacterium chimaera* has a HPLC profile that distinguishes it from that of other members of the *Mycobacterium avium* complex.

16. **Mycobacterium colombiense** Murcia, Tortoli, Menendez, Palenque and Garcia 2006, 2053[VP]

co.lom.bi.en′se. N.L. neut. adj. *colombiense* of or belonging to Colombia, the South American country where the strains were first isolated.

Acid-fast nonmotile rods. Visible growth of non-pigmented, rough colonies appears on Löwenstein–Jensen medium and on Ogawa Kudoh and Sauton agars in 3 weeks. Some colonies may develop yellowish pigmentation with age. Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. Temperature range for growth is 20–37°C. Strains show a relationship to members of the *Mycobacterium avium* complex. They hybridize with probes for the *Mycobacterium avium* complex in the widely used Accuprobe identification system. However, *Mycobacterium colombiense* differs from other members of the *Mycobacterium avium* complex in producing urease. Differential characteristics of slowly growing species are shown in Table 37.

Source: the type strain was isolated from the blood of an HIV-positive patient in Colombia.

DNA G+C content (mol%): not determined.

Type strain: CIP 108962.

Sequence accession nos: AM062764 (16S rRNA gene), AM062764 (ITS-1), AM062765 (*hsp65*).

Additional remarks: Mycobacterium colombiense can be distinguished from members of the *Mycobacterium avium* complex by its unique 16S rRNA gene sequence and by DNA–DNA relatedness data. Additionally, although *Mycobacterium colombiense* shows an *hsp*65 sequence identical to that of *Mycobacterium avium* variant I (av-I), it also displays a unique ITS-1 sequence (MAC-X).

The *Mycobacterium ulcerans* clade

17. **Mycobacterium ulcerans** MacCallum, Tolhurst and Buckle *in* Fenner 1950, 817[AL]

ul′ce.rans. L. part. adj. *ulcerans* making sore, causing to ulcerate.

Acid-fast, Gram-stain-positive, moderately long rods. Growth on inspissated egg medium is evident after incubation for 4 weeks at 30–33°C as minute, transparent, domed colonies. On ageing, colonies become convex to flat, with irregular outlines, and have a rough, yellow surface. Rough, corded colonies develop on oleic acid-albumin agar. Weak growth is observed at 25°C, but does not grow at 37°C. In contrast to its close relative *Mycobacterium marinum*, *Mycobacterium ulcerans* does not adapt to growth at 37°C on repeated subculture. TLC of methanolysates shows the presence of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Mycobacterium ulcerans has been recovered from ulcerative skin infections of humans in Malaya, Mexico, New Guinea, and on the African continent (Boisvert, 1977). Skin ulcers in humans are characterized by indolent extensions from areas of inconspicuous induration to involvement of large areas with undermining edges. Mice and rats can be infected experimentally; but not fowls, guinea pigs, lizards, or rabbits. Experimentally inoculated rats develop hemorrhagic necrotic lesions surrounded by zones of cellular

accumulations consisting of leukocytes, lymphocytes, and macrophages, but without giant cells. The necrotic and cellular zones show large clumps of acid-fast bacilli in the extracellular spaces and in macrophages. In experimental animals, lesions develop only in cooler parts of the body. Inoculation of mouse footpads consistently causes local lesions. Inoculation by the intranasal, intraperitoneal, or intravenous route does not cause visceral lesions, but a long incubation results in ulcerating lesions in hairless peripheral parts of the body and on the scrotum (Fenner, 1956). The characteristic necrosis is associated with an extracellular heat-labile toxin with a molecular mass of approximately 105 (Read et al., 1974). Human lesions do not show inflammatory responses, but consist of areas of lipid necrosis and tissue breakdown.

Source: originally isolated from a human skin lesion in Australia.

DNA G+C content (mol%): 65.4 (whole-genome sequencing).

Type strain: ATCC 19423, CIP 105425, NCTC 10417.

Sequence accession no. (16S rRNA gene): X88926.

Additional remarks: Mycobacterium ulcerans appears to be closely related to *Mycobacterium marinum* as both species have identical 16S rRNA gene and ITS sequences (Portaels et al., 1996; Roth et al., 1998). However, only the *Mycobacterium ulcerans* genome contains the insertion sequence *IS*2404 (Stinear et al., 1999). Additionally, *Mycobacterium ulcerans* causes a more progressive, malignant disease than *Mycobacterium marinum* and is found in tropical regions whereas *Mycobacterium marinum* is common in temperate climates. The name "*Mycobacterium buruli*", which has no formal standing in nomenclature, was applied to strains isolated in Uganda (Clancey, 1964). "*Mycobacterium buruli*" strains are considered to be members of *Mycobacterium ulcerans* on the basis of biochemical (Schröder, 1975) and immunological (Stanford and Grange, 1974) data.

18. **Mycobacterium marinum** Aronson 1926, 320[AL]

ma.ri'num. L. neut. adj. *marinum* of the sea, marine.

Acid-fast, moderate to long rods with frequent cross barring. Colonies are smooth to rough on Löwenstein–Jensen medium and Middlebrook agar after incubation for 7 or more days at 30°C. On primary isolation, growth is restricted to the temperature range 25–35°C, but adaptation to 37°C may occur after several subcultures. Colonies are photochromogenic; they show no pigmentation in the dark, but when grown in light or exposed to light when colonies are young, they develop a brilliant yellow color. TLC of methanolysates shows α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

In humans, *Mycobacterium marinum* may cause skin lesions resulting from infection of abrasions incurred in swimming pools or fish tanks. Causes cutaneous granulomas ("swimming pool granuloma"), usually on elbows, fingers, forearms, or wrists, but also can occur on feet, knees, and toes. Papules or nodules occur which may ulcerate. Healing may be spontaneous over a period of some months (Norden and Linell, 1951; Schaefer and Davis, 1961). However, chemotherapy may often be required.

Mice receiving a large inoculum intraperitoneally develop ulcerations on paws, scrotum, and tail; visceral lesions and death sometimes occur. Following intravenous inoculation, lesions are limited to the tail. Footpad inoculations lead to local swelling and some ulceration (Fenner, 1956). Guinea pigs inoculated subcutaneously or by inhalation do not exhibit disease; intraperitoneal inoculation occasionally leads to scrotal lesions. Rats inoculated intraperitoneally do not develop disease, but nodules occur in the omentum and hilar lymph nodes. Rabbits develop local lesions when inoculum is applied to abraded skin sites and they may develop granuloma with caseous necrosis in the scrotum after intraperitoneal or intravenous inoculation. Representatives of 50 poikilothermic species (amphibians, fish, and reptiles) have been found susceptible to fatal systemic infection when maintained at 30°C (Clark and Shepard, 1963).

Source: isolated from diseased fish and aquaria.

DNA G+C content (mol%): 65.7 (whole-genome sequencing).

Type strain: ATCC 927, CCUG 20998/27843, CIP 104528, DSM 44344, JCM 12275, NCTC 2275.

Sequence accession no. (16S rRNA gene): AF456240.

Additional remarks: Mycobacterium marinum strains have also been classified under the invalid names "*Mycobacterium balnei*" and "*Mycobacterium platypoecilus*". However, Castelnuovo and Morellini (1962), employing immunoelectrophoretic analysis, concluded that these organisms represented a single species. Magnusson (1967) distinguished *Mycobacterium marinum* from 10 other mycobacterial species, including *Mycobacterium kansasii*, by dermal hypersensitivity. One agglutinating serovar was originally recognized and cross-reaction is not seen with *Mycobacterium kansasii* by this technique, by immunodiffusion with phenol-soluble antigen (Wayne, 1971), or by immunofluorescence (Jones and Kubica, 1968). A second serovar has been proposed (Goslee et al., 1976). Stanford and Grange (1974) detected three antigens by immunodiffusion that were shared by "*Mycobacterium balnei*" and *Mycobacterium marinum*, but not by other mycobacterial species. A large structural divergence between the T-catalase of *Mycobacterium marinum* and those of *Mycobacterium avium* and *Mycobacterium kansasii* has been detected serologically (Wayne and Diaz, 1982). Numerical taxonomic studies concluded that members of *Mycobacterium marinum* form a discrete cluster (Wayne et al., 1978; Wayne et al., 1991). *Mycobacterium marinum* appears to be closely related to *Mycobacterium ulcerans*; both species show only minor variations in 16S rRNA gene and ITS sequences (Portaels et al., 1996; Roth et al., 1998). However, only the *Mycobacterium ulcerans* genome contains the insertion sequence *IS*2404 (Stinear et al., 1999).

19. **Mycobacterium shottsii** Rhodes, Kator, Kotob, van Berkum, Kaattari, Vogelbein, Quinn, Floyd, Butler and Ottinger 2003, 423[VP]

shot'tsi.i. N.L. gen. masc. n. *shottsii* of Shotts, named after Emmett Shotts, an American fish bacteriologist.

Acid-fast, coccobacilli (0.8–1 × 0.4–0.6 μm), which may form cell aggregates in culture. Visible growth is observed from dilute inocula after incubation at 23°C for 4–6 weeks. Little or no growth occurs at 30°C and none occurs at 37°C

or above. Colonies on Middlebrook 7H10 agar are small (0.5–1.0 mm), dysgonic, rough, non-pigmented, and typically flat with an irregular margin, becoming umbonate on ageing. Smooth colonies with an entire margin are seen less frequently. Growth does not occur on MacConkey agar (without crystal violet) or on 5% (w/v) NaCl agar. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from striped bass (*Morone saxatilis*) during an epizootic of mycobacteriosis in Chesapeake Bay, Maryland, USA.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700981, JCM 12657, NCTC 13215.

Sequence accession no. (16S rRNA gene): AY005147.

Additional remarks: this species shares a high 16S rRNA gene sequence similarity to *Mycobacterium marinum* and *Mycobacterium ulcerans* (99.2%), but differs from it in some phenotypic characteristics and is unusual in displaying a positive niacin test. See also comments under the description of *Mycobacterium pseudoshottsii*.

20. **Mycobacterium pseudoshottsii** Rhodes, Kator, McNabb, Deschayes, Reyrat, Brown-Elliot, Wallace, Trott, Parker, Lifland, Osterhout, Kaattari, Reece, Vogelbein and Ottinger 2005, 1144[VP]

pseu.do.shot′tsi.i. Gr. adj. *pseudês* false; N.L. gen. n. *shottsii* name of a species; N.L. gen. n. *pseudoshottsii* a false *Mycobacterium shottsii*, not the true *Mycobacterium shottsii*.

Acid-fast coccobacilli (0.8–1.0 × 0.4–0.6 µm) which form cell aggregates in culture. Visible growth is observed after 4–6 weeks incubation at 23°C from dilute inocula. Little or no growth occurs at 30°C and none occurs at 37°C or above. Colonies on Middlebrook 7H10 agar are small (1–3 mm), rough, photochromogenic, and typically flat with an irregular margin, becoming umbonate on ageing. A pale yellow to gold pigment develops following exposure to light and intensifies with age. Does not grow on MacConkey agar (without crystal violet) or on 5% (w/v) NaCl agar. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from granulomatous lesions in splenic tissue from a striped bass (*Morone saxatilis*) during an epizootic of mycobacteriosis in Chesapeake Bay, Maryland, USA.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-883, NCTC 13318.

Sequence accession nos: AY570988 (16S rRNA gene); AY571788 (*hsp65*).

Additional remarks: despite sharing some phenotypic characters and a common host, this species can be clearly differentiated from *Mycobacterium shottsii* on the basis of key phenotypic characters and on 16S rRNA gene, *erp*, and *hsp65* gene sequencing. However, on the basis of 16S rRNA and *hsp65* gene sequences, it is very similar to scotochromogenic species isolated from Mediterranean fish and described as strains of *Mycobacterium marinum* by Ucko et al. (2002).

The *Mycobacterium gordonae* clade

21. **Mycobacterium gordonae** Bojalil, Cerbón and Trujillo 1962, 344[AL]

gor.do′na.e. N.L. gen. fem. n. *gordonae* of Gordon, named after the American bacteriologist Ruth E. Gordon.

Cells are moderate to long rods. Colonies on Löwenstein–Jensen medium and Middlebrook agar are usually smooth, soft, and yellow- or orange-pigmented after incubation for 7 d. Pigment is produced when grown in the dark, but is often intensified when grown in continuous light. Temperature range for growth is 28–37°C; optimal temperature is 35°C; does not grow at 45°C. TLC of methanolysates shows the presence of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Rarely, if ever, implicated in human disease but it has been considered to cause infections in severely immunocompromised individuals (Lessnau et al., 1993; Wolinsky, 1979a).

Source: frequently encountered as a casual resident in human sputum and gastric lavage specimens; also found in water taps and soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 14470, CCUG 21801/21811, CIP 104529, DSM 44160, JCM 6382, NCTC 10267.

Sequence accession no. (16S rRNA gene): X52923.

Additional remarks: at one time, many *Mycobacterium gordonae* strains were referred to by the illegitimate name "*Mycobacterium aquae*" though the "type strain" of "*Mycobacterium aquae*" had the properties of *Mycobacterium smegmatis* (Wayne, 1970). The name "*Mycobacterium aquae*" was then applied to strains that resembled *Mycobacterium gordonae*, but yielded a different TLC pattern (Jenkins et al., 1972). In Opinion 55, the Judicial Commission placed the name "*Mycobacterium aquae*" on the list of *nomina rejicienda* (Judicial Commission of the International Committee on Systematic Bacteriology, 1982).

Immunodiffusion analysis of bacillary extracts demonstrates five precipitin lines unique to *Mycobacterium gordonae* (Stanford and Grange, 1974). Members of the species were not agglutinated by sera produced against *Mycobacterium avium*, *Mycobacterium intracellulare*, *Mycobacterium kansasii*, *Mycobacterium marinum*, or *Mycobacterium scrofulaceum* (Hobby et al., 1967). Seven agglutinating serovars of *Mycobacterium gordonae* were proposed by Goslee et al. (1976). Their surface lipid antigens yielded characteristic chromatographic patterns (Jenkins et al., 1972), which are of the alkali-labile type associated with *Mycobacterium kansasii* rather than the alkali-stable type seen with *Mycobacterium scrofulaceum* (Brennan, 1981).

22. **Mycobacterium asiaticum** Weiszfeiler, Karasseva and Karczag 1971, 247[AL]

a.si.a′ti.cum. L. neut. adj. *asiaticum* Asiatic, of Asia.

Acid-fast coccoid rods. Growth on inspissated egg medium is dysgonic after incubation for 15–21 d at 37°C. Strains are usually photochromogenic, but occasionally fail to develop pigment after exposure to light; pigment is not produced in the dark (Wayne et al., 1981). TLC of methanolysates shows the presence of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Produces focal lung lesions after intravenous inoculation of mice; may kill mice within 30–60 d (Weiszfeiler et al., 1971).

Source: original strains were isolated from monkeys, but one strain has been considered to be the cause of human lung disease (Wayne et al., 1981).

DNA G+C content (mol%): not determined.

Type strain: ATCC 25276, CCUG 29115, CIP 106809, DSM 44297, JCM 6409.

Sequence accession no. (16S rRNA gene): AF480595.

Additional remarks: Mycobacterium asiaticum strains group in a cluster that is distinct from that of *Mycobacterium gordonae* on numerical taxonomic analysis, but only pigmentation provides a simple criterion for distinguishing between these species (Wayne et al., 1981). Intradermal skin testing demonstrated homogeneity of the species and confirmed separation from five other mycobacterial species including *Mycobacterium simiae*, but no comparison was made with *Mycobacterium gordonae* (Baess and Magnusson, 1982). *Mycobacterium asiaticum* has a very low DNA homology to *Mycobacterium simiae*, but has not been compared with *Mycobacterium gordonae* (Baess and Magnusson, 1982).

The *Mycobacterium interjectum* clade

23. **Mycobacterium interjectum** Springer, Kirschner, Rost-Meyer, Schröder, Kroppenstedt and Böttger 1993, 3088[VP]

in.ter.jec′tum. L. v. *interjacio* to set, place, or put between; L. neut. part. adj. *interjectum* placed between, corresponding to the phylogenetic position between rapid and slow-growing mycobacteria.

Acid–alcohol-fast, rod-shaped coccobacilli (0.7–2.0 × 0.6–1.0 μm) which are often pleomorphic and may exhibit filaments (up to 6.0 μm). Spores, capsules, and aerial hyphae do not occur. Visible growth from dilute inocula requires incubation for 3–4 weeks. Colonies on Löwenstein–Jensen medium are dysgonic, smooth, scotochromogenic, yellowish in color, and 1–2 mm in diameter. Temperature range for growth is 31–37°C; does not grow at 22 or 41°C. TLC of methanolysates shows the presence of α-, keto-, and epoxy-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from an 18-month-old child with cervical lymphadenitis.

DNA G+C content (mol%): not determined.

Type strain: DSM 44064, CCUG 37514, ATCC 51457.

Sequence accession no. (16S rRNA gene): X70961.

24. **Mycobacterium saskatchewanense** Turenne, Thibert, Williams, Burdz, Cook, Wolfe, Cockcroft and Kabani 2004b, 665[VP]

sas.kat.che.wa.nen′se. N.L. neut. adj. *saskatchewanense* of or pertaining to Saskatchewan.

Acid–alcohol-fast, long, beaded rods. Colonies on Middlebrook 7H10 agar develop after incubation for 2–4 weeks; they are initially transparent, but mature colonies show a bright yellow scotochromogenic pigmentation in a raised center, and a transparent irregular apron. Growth on Löwenstein–Jensen medium is rough and dry in texture. Some strains show a thin film of growth on MacConkey agar (without crystal violet), but growth does not occur on media supplemented with 5% (w/v) NaCl. Temperature range for growth is 25–37°C; optimal temperature for growth is 37°C; does not grow at 42°C. Differential characteristics of slowly growing species are shown in Table 37.

Strains have been isolated from respiratory samples, but without proven disease involvement, suggesting that this species may be an opportunistic pathogen for humans.

Source: isolated from sputum samples from an elderly female patient with bronchiectasis and a recurrent chest infection.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-544, CIP 108114, DSM 44616, JCM 13016.

Sequence accession no. (16S rRNA gene): AY208856.

Additional remarks: PCR/restriction enzyme sequence analysis of the *hsp65* gene revealed a close relationship between *Mycobacterium saskatchewanense* and *Mycobacterium interjectum*; a relationship supported by similarity of HPLC profiles of some strains assigned to *Mycobacterium interjectum* (although not the type strain). *Mycobacterium saskatchewanense* strains hybridize with the commonly used *Mycobacterium avium* complex hybridization probe (AccuProbe), but not with specific probes, they are also phenotypically distinct from *Mycobacterium avium* and *Mycobacterium intracellulare*. Additionally, HPLC profiling suggests a similarity to *Mycobacterium palustre*. It is clear that without sequence-based identification *Mycobacterium saskatchewanense* may be difficult to recognize (Turenne et al., 2004b).

The *Mycobacterium palustre* clade

25. **Mycobacterium palustre** Torkko, Suomalainen, Livanainen, Tortoli, Suutari, Seppänen, Paulin and Katila 2002, 1524[VP]

pa.lus′tre. L. neut. adj. *palustre* living in swamps, referring to the isolation of the organisms from peat land run-off water.

Acid–alcohol-fast bacilli. Visible growth from dilute inocula occurs following incubation for 2–3 weeks; mature colonies require incubation for 4–5 weeks. Colonies on Löwenstein–Jensen medium and on Middlebrook agar are yellow to pale yellow, smooth and scotochromogenic at 36°C, and photo- or scotochromogenic at 42°C. Temperature range for growth is 30–42°C; optimal growth is at 36°C; growth at 45°C requires heavy inocula and incubation for 5–6 weeks. Differential characteristics of slowly growing species are shown in Table 37.

Source: the description of the species is based on 13 isolates, eight of which were cultured from water samples collected from Finnish streams (Livanainen et al., 1993), two from sputum samples, one from a submandibular lymph node biopsy of a child, and two from submandibular tissue of pigs.

DNA G+C content (mol%): not determined.

Type strain: DSM 44572, ATCC BAA-377.

Sequence accession no. (16S rRNA gene): AJ308603.

Additional remarks: all clinical, environmental, and veterinary strains of this species hybridize with the commonly used *Mycobacterium avium* complex hybridization probe (AccuProbe), but not with the species-specific probes for *Mycobacterium avium* and *Mycobacterium intracellulare*.

26. **Mycobacterium parascrofulaceum** Turenne, Cook, Burdz, Pauls, Thibert, Wolfe and Kabani 2004b, 1550[VP]

pa.ra.scro.fu.la′ce.um. Gr. prep. *para* like; N.L. neut. adj. *scrofulaceum* specific epithet of a bacterial species; N.L. neut.

adj. *parascrofulaceum* beside *Mycobacterium parascrofulaceum* (referring to the phenotypic resemblance of the isolate to *Mycobacterium scrofulaceum*).

Pleomorphic acid-fast bacilli which show moderate beading. Colonies on Löwenstein–Jensen medium and on Middlebrook 7H10 agar grow within 2–4 weeks and are scotochromogenic with yellow to orange pigmentation. Most strains form smooth and domed colonies, but dry-wrinkled and mucoid forms can occur. Does not grow on MacConkey agar or on 5% (w/v) NaCl agar. Temperature range for growth is 25–37°C; optimal growth is at 37°C; does not grow at 42°C. Differential characteristics of slowly growing species are shown in Table 37.

Source: most isolates are derived from human respiratory samples and in at least one case the organism was believed to be clinically significant.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-614, DSM 44648, JCM 13015.

Sequence accession no. (16S rRNA gene): AY337273.

Additional remarks: this species was described after further characterization of strains initially assigned to *Mycobacterium scrofulaceum*. The organism is biochemically and morphologically indistinguishable from *Mycobacterium scrofulaceum*; HPLC of lipids shows that the species is almost identical to organisms of the *Mycobacterium avium* complex and some strains of *Mycobacterium scrofulaceum*. *Mycobacterium parascrofulaceum* is misidentified as *Mycobacterium scrofulaceum* with some commercial genotyping systems. Turenne et al. (2004a) found 16S rRNA gene sequence analysis established *Mycobacterium parascrofulaceum* as a distinct species related to *Mycobacterium palustre* and *Mycobacterium simiae*. The 16S rRNA gene phylogenetic tree indicates a relationship to *Mycobacterium palustre*, but a somewhat tenuous one to *Mycobacterium simiae* (Figure 86).

27. **Mycobacterium kubicae** Floyd, Gross, Bonato, Silcox, Smithwick, Metchock, Crawford and Butler 2000, 1814[VP]

ku.bi′ca.e. N.L. gen. masc. n. *kubicae* of Kubica, to honor the contributions of George P. Kubica, an exceptional American mycobacteriologist, mentor, and teacher.

Acid–alcohol-fast, generally rod-shaped cells that frequently bent with occasional coccoid forms (0.25–7.0 × 0.25–0.5 μm). Does not show branching or the formation of aerial mycelia. Colonies are yellow-colored and scotochromogenic. Smooth, domed growth occurs on Middlebrook 7H11 agar and film-like growth is seen on Löwenstein–Jensen medium. Temperature range for growth is 28–37°C on Middlebrook agar, but for most isolates is confined to 33–37°C on Löwenstein–Jensen medium; does not grow at 42°C. TLC of methanolysates shows the presence of α-, keto- and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: fifteen isolates were obtained from throughout the United States. Eight were from sputum, three were from bronchial washings, and four were from unspecified sources.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700732, CIP 106428, DSM 44627, JCM 13573.

Sequence accession no. (16S rRNA gene): AF133902.

The *Mycobacterium simiae* clade

28. **Mycobacterium simiae** Karassova, Weiszfeiler and Kraznay 1965, 282[AL]

si.mi′a.e. L. n. *simia* the ape; L. gen. *simiae* of the ape.

Short acid-fast rods. Smooth colonies develop on inspissated egg medium after incubation for 2–3 weeks. Usually photochromogenic, but sometimes fails to produce pigment on exposure to light. Temperature range for growth is 25–37°C; optimal growth is at 37°C; does not grow at 45°C. TLC of methanolysates shows the presence of α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Three agglutinating serovars, labeled simiae 1, simiae 2 and avian 18, have been recognized in strains identified as *Mycobacterium simiae* (Meissner and Schröder, 1975; Wayne et al., 1983). Reciprocal intradermal skin testing demonstrated a single cluster for the species, with subtle distinctions between strains of simiae serovars 1 and 2; avian serovar 18 was not included in the study (Baess and Magnusson, 1982). Immunoelectrophoretic analysis of bacillary extracts demonstrated many antigens shared between simiae 1 and 2 serovars and with *Mycobacterium szulgai* (Wayne et al., 1981).

Source: initially isolated from lymph nodes of apparently healthy monkeys (Karassova et al., 1965); the species has since been implicated in cases of human pulmonary disease (Wolinsky, 1979a). The organisms multiply extensively in organs of mice.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25275, CCUG 29114/42427, CIP 104531, DSM 44165, JCM 12377.

Sequence accession no. (16S rRNA gene): X52931.

Additional remarks: numerical taxonomic analysis shows *Mycobacterium simiae* to be comprised of a highly homogeneous cluster of strains of serovar 18 and a less tightly linked subcluster of the other two serovars (Wayne et al., 1983). Serovar 18 strains yield a negative niacin test, whereas the others give a positive one. Serovar 1 and 2 strains have been distinguished from one another in DNA–DNA relatedness studies, but not at a level sufficient to justify the establishment of another species (Baess and Magnusson, 1982). Strains previously designated "*Mycobacterium habana*" (Valdivia et al., 1971) are included in *Mycobacterium simiae* serovar 1 (Meissner and Schröder, 1975).

29. **Mycobacterium florentinum** Tortoli, Rindi, Goh, Katila, Mariottini, Mattei, Mazzarelli, Suomalainen, Torkko and Rastogi 2005, 1105[VP]

flo.ren.ti′num. L. neut. adj. *florentinum* of or belonging to *Florentia*, the Italian city of Florence, from where the majority of the strains were collected and investigated.

Acid-fast, nonmotile, non-capsulated, asporogenous rods. Colonies on Löwenstein–Jensen medium are smooth, creamy, and non-chromogenic and appear after incubation for 2 weeks. Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. Temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows the presence of α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: description is based on eight strains isolated from human clinical samples; seven from sputa of different patients and the type strain, which was isolated from an excised lymph node of a young girl. One strain, isolated from a severe pulmonary infection in Finland, was considered to be a sequevar of *Mycobacterium triplex* (Suomalainen et al., 2001).

DNA G+C content (mol%): not determined.

Type strain: DSM 44852, CCUG 50992, CIP 108409.

Sequence accession no. (16S rRNA gene): AJ616230.

30. **Mycobacterium heidelbergense** Haas, Butler, Kirschner, Plikaytis, Coyle, Amthor, Steigerwalt, Brenner, Salfinger, Crawford, Böttger and Bremer 1998, 627[VP] (Effective publication: Haas, Butler, Kirschner, Plikaytis, Coyle, Amthor, Steigerwalt, Brenner, Salfinger, Crawford, Böttger and Bremer 1997, 3208.)

hei.del.ber.gen′se. N.L. neut. adj. *heidelbergense* of or belonging to Heidelberg, Germany, the source of the strain on which the description of the species is based.

Acid–alcohol-fast coccobacilli (2.0–3.0 × 0.5–0.8 μm) though pleomorphic forms may occur (up to 8.0 μm in length). Aerial hyphae, capsules, and spores are absent. Initial isolation was made in Middlebrook 7H12 liquid medium. Visible growth from dilute inocula appears on Löwenstein–Jensen medium in 3–4 weeks. Colonies are eugonic, dome-shaped, smooth, non-pigmented, and 0.5–1.0 mm in diameter. Temperature range for growth is 30–37°C; optimal growth is at 33–35°C; does not grow at 25 or 45°C. However, colonies may be observed on Middlebrook 7H11 agar at temperatures ranging between 25 and 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: originally isolated from cervical lymph node tissue of a child suffering from lymphadenitis.

DNA G+C content (mol%): not determined.

Type strain: ATCC 51253, CIP 105424, DSM 44471.

Sequence accession no. (16S rRNA gene): AJ000684.

31. **Mycobacterium triplex** Floyd, Guthertz, Silcox, Duffey, Jang, Desmond, Crawford and Butler 1996, 2966[VP]

tri′plex. L. neut. adj. *triplex* threefold, triple, referring to something consisting of three parts, specifically, the triple-cluster HPLC pattern shown by these isolates.

Acid–alcohol-fast, short rods to coccoid forms. Colonies on Löwenstein–Jensen medium and Middlebrook 7H10 agar after 14–21 d are cream to buff, non-pigmented, usually smooth, sometimes appearing rough with age. Does not grow on media containing 5% (w/v) NaCl. Temperature range for growth is 30–37°C; does not grow at 25°C or 42°C. HPLC analysis of mycolic acids results in a three-cluster mycolate pattern, resembling that of *Mycobacterium simiae.* Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from cerebrospinal fluid, lymph nodes, and sputum of 10 patients from various locations within the USA.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700071, CIP 106108, DSM 44626.

Sequence accession no. (16S rRNA gene): U57632.

Additional remarks: the incorrect accession number quoted in the effective publication (ATCC 70071) was corrected in Validation List no. 61, footnote d [Int. J. Syst. Bacteriol. *47*: 601–602 (1997)].

32. **Mycobacterium montefiorense** Levi, Bartell, Gandolfo, Smole, Costa, Weiss, Johnson, Osterhout and Herbst 2003, 2151[VP]

mon.te.fio.ren′se. N.L. neut. adj. *montefiorense* of or pertaining to Montefiore, referring to the Montefiore Medical Center, Bronx, New York, where the organism was isolated.

Acid-fast, beaded cells which are rod-shaped on Middlebrook 7H10 agar, though cocco-bacillary forms occur after long incubation (20 weeks) on sheep blood agar. Small, transparent, non-chromogenic colonies are formed on Middlebrook agar which are biochemically inactive. Colonies on sheep blood agar are rough and α-hemolytic. Growth occurs at 22–25°C, but not at 30°C or above. Does not grow on media containing 5% (w/v) NaCl. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from a granulomatous skin lesion of a moray eel. Considered to be the etiological agent of granulomatous skin disease in moray eels as it produced a fatal outbreak in a captive population (Herbst et al., 2001).

DNA G+C content (mol%): not determined.

Type strain: DSM 44602, CCUG 51898, ATCC BAA-256.

Sequence accession no. (16S rRNA gene): AF330038.

33. **Mycobacterium genavense** Böttger, Hirschel and Coyle 1993, 842[VP]

ge.na.ven′se. L. neut. adj. *genavense* of or belonging to Geneva, the source of the first isolate.

Cells in tissues and in broth are small, clumped, acid-fast coccobacilli (2.0 × 1.0 μm). The organism is asporogenous, non-capsulate, and lacks aerial hyphae. It is highly fastidious; growth does not occur on standard solid media used for the isolation of mycobacteria, such as Löwenstein–Jensen medium, Middlebrook 7H10 agar, and unsupplemented Middlebrook 7H11 agar. Primary isolation requires broth media (Middlebrook 7H9 or 7H12) and incubation for 3–12 weeks. Growth is facilitated in acid broth media (Hoop et al., 1993). When inoculated with a broth culture suspension, visible growth on Middlebrook 7H11 agar supplemented with mycobactin J requires 3–9 weeks. Growth consists of tiny, transparent, non-photochromogenic, dysgonic colonies. Variant eugonic colonies which are either dense and creamy or flat and dry may be formed in older cultures. Cells from creamy colonies are pleomorphic ranging in length from 1.0 to 6.0 μm; the majority are approximately 2.0 μm long and may occur in clumps. Cells from dry colonies are similar but are more variable in length, somewhat curved, and show more clumping. After incubation for more than 3 months, the predominant cells are coccoid, short rods (1.0–2.0 μm in length), which frequently occur in clumps. Temperature range for growth is 25–42°C; optimal growth is at 42°C; does not grow at 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

The species is considered to be an opportunistic pathogen of severely immune-suppressed individuals.

Source: isolated from a variety of specimen types (blood, bone marrow, liver and intestine, lymph nodes, and spleen) from patients with AIDS. Most patients exhibit diarrhea, fever, and weight loss. Strains have been isolated from pet birds (Hoop et al., 1993).

DNA G+C content (mol%): not determined.

Type strain: ATCC 51234.

Sequence accession no. (16S rRNA gene): X60070.

34. **Mycobacterium parmense** Fanti, Tortoli, Hall, Roberts, Kroppenstedt, Dodi, Conti, Polonelli and Chezzi 2004, 1126[VP]

par.men′se. L. neut. adj. *parmense* of or belonging to *Parma*, the Italian city of Parma, where the strain was isolated.

Small, acid–alcohol-fast, asporogenous, non-capsulate, nonmotile, rod-shaped bacteria. Small (≤1 mm), round, smooth, scotochromogenic colonies raised with round or lobate regular margins are formed on Löwenstein–Jensen medium after incubation for 2 weeks. Does not grow on MacConkey agar (without crystal violet) or on 5% (w/v) NaCl agar. Temperature range for growth is 25–37°C; does not grow at 42°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from a cervical lymph node of a 3-year-old child with bilateral lymphadenitis.

DNA G+C content (mol%): not determined.

Type strain: CIP 107385, DSM 44553, CCUG 50998.

Sequence accession no. (16S rRNA gene): AF466821.

35. **Mycobacterium lentiflavum** Springer, Wu, Bodmer, Haase, Pfyffer, Kroppenstedt, Schröder, Emler, Kilburn, Kirschner, Telenti, Coyle and Böttger 1996b, 836[VP] (Effective publication: Springer, Wu, Bodmer, Haase, Pfyffer, Kroppenstedt, Schröder, Emler, Kilburn, Kirschner, Telenti, Coyle and Böttger 1996c, 1104.)

len.ti.fla′vum. L. adj. *lentus -a -um* slow; L. adj. *flavus -a -um* yellow; N.L. neut. adj. *lentiflavum* slow and yellow, two characteristic features of this species.

Acid–alcohol-fast coccobacilli. The organism does not produce aerial hyphae, capsules, or spores. Visible growth from dilute inocula appears in 3–4 weeks. Colonies on Löwenstein–Jensen medium are smooth, 1–2 mm in diameter, and show bright yellow scotochromogenic pigmentation. Temperature range for growth is 22–37°C; does not grow at 42–45°C. TLC of methanolysates shows the presence of α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from a variety of clinical samples, including an isolate from a patient with spondylodiscitis (type strain), four from gastric juice, four from sputum, and two from urine. Eleven isolates were identified as contaminants of a flexible fiber optic bronchoscope. Most isolates are fortuitous and probably represent colonization, but the source of the type strain indicates a potential for pathogenicity. Furthermore, the species has been identified as the cause of cervical lymphadenitis in a child (Haas et al., 1993).

DNA G+C content (mol%): 66.8 (HPLC).

Type strain: ATCC 51985, CCUG 42422/42559, CIP 105465, DSM 44418, JCM 13390.

Sequence accession no. (16S rRNA gene): X80769.

The *Mycobacterium celatum* clade

36. **Mycobacterium celatum** Butler, O'Connor, Yakrus, Smithwick, Plikaytis, Moss, Floyd, Woodley, Kilburn, Vadney and Gross 1993, 547[VP]

ce.la′tum. L. neut. part. adj. *celatum* hidden or concealed, referring to the concealed nature of these organisms among recognized *Mycobacterium* species.

Acid–alcohol-fast, slender, and predominantly rod-shaped cells with occasional coccoid forms (0.5–13.0 × 0.25–0.5 µm). May be somewhat filamentous, but does not exhibit cording or branching. Eugonic growth occurs on Löwenstein–Jensen medium at 33–42°C after incubation for 3–5 weeks. Dysgonic growth occurs at 27–30°C and notably at 45°C. Comparable results are found on Middlebrook 7H10 medium though growth is visible in 1 week. Mature colonies are polymorphic, usually small, smooth, dome-shaped, and either non-pigmented or pale yellow in older cultures. Flat and transparent colonies occur infrequently. Does not grow on MacConkey agar or on media containing 5% (w/v) NaCl. RFLP analysis of the *hsp65* gene gives two patterns, one of seven bands and one of six. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Clinically significant infections are being reported more frequently in immune-compromised individuals, such as AIDS patients (Piersimoni et al., 1997). Isolates may be mistaken for the phenotypically similar species *Mycobacterium xenopi* (Zurawski et al., 1997).

Source: most of the original 24 strains were isolated either from sputum, including the type strain, or from bronchial washings. Additional strains have been isolated from blood, spine, and stool samples. HIV status was known for 11 of the patients of whom seven were positive (Butler et al., 1993).

DNA G+C content (mol%): not determined.

Type strain: ATCC 51131, CCUG 39185, CIP 106109, DSM 44243, JCM 12373.

Sequence accession no. (16S rRNA gene): L08169.

37. **Mycobacterium branderi** Koukila-Kähkölä, Springer, Böttger, Paulin, Jantzen and Katila 1995, 552[VP]

bran′de.ri. N.L. gen. masc. n. *branderi* of Brander, referring to Eljas Brander, the former head of the Tuberculosis Laboratory of the National Public Health Institute, Finland, who collected the strains.

Delicate, slender, and often slightly curved (1.2–3.0 µm in length) acid-fast rods. Growth occurs on Middlebrook 7H11 agar after incubation for 2–3 weeks. Colonies are smooth, often umbonate, non-chromogenic, and off-white to grayish in color. Temperature range for growth is 25–45°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: the original description was based on respiratory

isolates obtained from nine patients, some of whom had cavitary mycobacteriosis of the lungs and were resistant to available drugs. In most cases, repeat samples from patients were positive for acid-fast bacilli and the only cultivable species was *Mycobacterium branderi*. Hence, this species must be considered as a potential human pathogen.

DNA G+C content (mol%): not determined.

Type strain: ATCC 51789, CIP 104592, DSM 44624, JCM 12687.

Sequence accession no. (16S rRNA gene): X82234.

The *Mycobacterium xenopi* clade

38. **Mycobacterium xenopi** Schwabacher 1959, 59[AL] [*Mycobacterium xenopei* (*sic*) Schwabacher 1959, 59]

xe.no′pi. N.L. n. *Xenopus* a genus of toad; N.L. gen. n. *xenopi* of *Xenopus*.

Acid-fast, long to filamentous rods, vary from 4–15 μm from *in vitro* cultures but are shorter in lesions; beading and palisade arrangements occur. Dilute inocula on Löwenstein–Jensen medium yield smooth, non-pigmented colonies after incubation at 37°C for 14 or more days; on ageing, most colonies become yellow. On Middlebrook 7H10 agar, uniquely characteristic colonies have compact centers, surrounded by a fringe of microscopically branching filaments on the agar surface. Colonies become adherent to the medium by a button-like growth into the agar (Runyon, 1968). Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. Growth is optimal at 40–45°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

The species is distinguished from other mycobacteria by reciprocal intradermal hypersensitivity reactions (Magnusson, 1980) and shows four species-specific antigens by immunodiffusion tests (Stanford and Grange, 1974). One agglutinating serovar has been reported (Goslee et al., 1976); the surface lipid antigen is of the alkali-labile type seen in *Mycobacterium kansasii*, not the stable type of *Mycobacterium avium* (Brennan, 1981).

Occasionally associated with chronic pulmonary disease, but often isolated from human secretions without associated disease; infrequently found in disease of the genitourinary tract (Wolinsky, 1979a). The organism has been associated with waterborne nosocomial outbreaks of disease (Gross et al., 1976). Experimental intraperitoneal inoculation of different strains in mice produces a variable response with limited numbers of macroscopic lesions appearing in the kidney, liver, lungs, or spleen. Guinea pigs receiving 4 mg intramuscularly develop caseous abscesses at the site of inoculation; 0.1 mg intra-cutaneously administered inocula cause swelling and ulceration at the inoculation site. Rabbits receiving 4 mg intramuscularly develop caseous abscesses at the site of inoculation (Engbaek et al., 1967; Schwabacher, 1959).

Source: first isolated from skin granulomas of the toad *Xenopus laevis* (Marks and Schwabacher, 1965).

DNA G+C content (mol%): not determined.

Type strain: NCTC 10042, ATCC 19250, DSM 43995, CCUG 28011/31306, CIP 104035.

Sequence accession no. (16S rRNA gene): AJ536033.

Additional remarks: Mycobacterium xenopi forms a discrete, compact cluster in numerical taxonomic studies (Meissner et al., 1974) and it is well separated from other species on the basis of immunological distances of T-catalase (Wayne and Diaz, 1982). DNA–DNA relatedness values are less than 30% against *Mycobacterium avium*, *Mycobacterium scrofulaceum*, and *Mycobacterium tuberculosis* (Baess, 1979).

39. **Mycobacterium heckeshornense** Roth, Reischl, Schönfeld, Naumann, Emler, Fischer, Mauch, Loddenkemper and Kroppenstedt 2001, 264[VP] (Effective publication: Roth, Reischl, Schönfeld, Naumann, Emler, Fischer, Mauch, Loddenkemper and Kroppenstedt 2000, 4106.)

hec.kes.hor.nen′se. N.L. neut. adj. *heckeshornense* of or belonging to Heckeshorn, a peninsula in Berlin, Germany, the location of the hospital in which the strain was found.

Gram-stain-positive, acid-fast, non-spore-forming, non-motile, short rods, occasionally pleomorphic, but without branching. Colonies are small, smooth, round, and scotochromogenic with a yellow color, appearing after incubation for 4 weeks. Better growth is observed on Middlebrook agar and broth media than on Löwenstein–Jensen medium. Temperature range for growth is 37–45°C; optimal growth is at 42°C; does not grow at 50°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from sputum and bronchoscopy samples from an immunocompetent young woman and was the cause of bilateral cavitary lung disease.

DNA G+C content (mol%): not determined.

Type strain: DSM 44428, CCUG 51897.

Sequence accession no. (16S rRNA gene): AF174290.

40. **Mycobacterium botniense** Torkko, Suomalainen, Livanainen, Suutari, Tortoli, Paulin and Katila 2000, 288[VP]

bot.ni.en′se. N.L. neut. adj. *botniense* of or belonging to *Botnia Occidentalis*, referring to the Latin name of the Västerbotten province (West Bothnia) of Finland where the organism was isolated.

Visible growth is observed from dilute inocula on egg media and on Middlebrook 7H11 agar following incubation for 5–8 weeks. Growth is enhanced on egg media and at lower pH values (5.5–6.5). Colonies are small, dysgonic, and scotochromogenic; a yellow pigment is produced. Temperature range for growth is 36–50°C; does not grow at 30°C. *Mycobacterium botniense* shows similarity in growth characteristics and biochemical properties to *Mycobacterium xenopi* and may have been misidentified for this species. GLC-MS analysis showed two unusual fatty acids, 2,4,6,x-tetramethyl-eicosanoic acid and 2,4,6,x,x-pentamethyl-docosanoic acid. Clear differentiation requires detailed GLC-MS analysis of fatty acids or 16S rRNA gene sequencing. Differential characteristics of slowly growing species are shown in Table 37.

Source: the original strains were isolated from stream water that had a high organic matter content and low pH and drained a peat land area. The organism has not been isolated from clinical samples.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700701, CCUG 47976, CIP 106753, DSM 44537.

Sequence accession no. (16S rRNA gene): AJ012756.

The *Mycobacterium terrae* clade

41. **Mycobacterium terrae** Wayne 1966, 922[AL]

ter′ra.e. L. n. *terra* earth. L. gen. n. *terrae* of the earth.

Acid–alcohol-fast bacilli. Visible growth from dilute inocula occurs on Löwenstein–Jensen medium after 7 d or more if required. Colonies are nonchromogenic, pale buff to white. Temperature range for growth is 22–37°C; does not grow at 42°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Produces neither local nor systemic lesions after intradermal inoculation of 10^{-1} mg in guinea pigs.

Source: isolated from human gastric lavage and sputum specimens; considered casual residents rather than pathogens. The species has also been isolated from soil (Wolinsky and Rynearson, 1968).

DNA G+C content (mol%): not determined.

Type strain: ATCC 15755, CCUG 27847, CIP 104321, DSM 43227, JCM 12143.

Sequence accession no. (16S rRNA gene): X52925.

Additional remarks: "*Mycobacterium novum*" Tsukamura 1967b, 163 is regarded as a synonym of *Mycobacterium terrae* Wayne (Meissner et al., 1974). "*Mycobacterium terrae*" Tsukamura 1967b is an invalidly proposed synonym for *Mycobacterium nonchromogenicum* Tsukamura 1965 and is not to be confused with *Mycobacterium terrae* Wayne 1966. See also discussion on *Mycobacterium nonchromogenicum. Mycobacterium triviale* shares many diagnostic features with *Mycobacterium nonchromogenicum* and *Mycobacterium terrae* (see below), but can be separated from them, notably by its consistent ability to grow in the presence of 5% (w/v) NaCl (Kubica et al., 1970).

42. **Mycobacterium kumamotonense** Masaki, Ohkusu, Hata, Fujiwara, Iihara, Yamada-Noda, Nhung, Hayashi, Asano, Kawamura and Ezaki 2007, 433[VP]

ku.ma.mo.to.nen′se. N.L. neut. adj. *kumamotonense* of or pertaining to Kumamoto Prefecture in Japan, where the type strain was isolated.

Acid–alcohol-fast, short rods. Colonies (1–2 mm diameter) are smooth, nonchromogenic, and raised with round or lobate regular margins on Middlebrook 7H9 agar and on 2% Ogawa medium after incubation for 7–14 d. Neither spores nor capsules are observed. Temperature range for growth is 25–42°C. Does not grow on media supplemented with 5% (w/v) NaCl. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: the type strain was isolated from the sputum of a 57-year-old female patient in Japan.

DNA G+C content (mol%): 67.4 (HPLC).

Type strain: CCUG 51961, JCM 13453.

Sequence accession nos: AB239925 (16S rRNA gene); AB239920 (*hsp65*); AB239919 (*rpoB*).

Additional remarks: initially proposed by Masaki et al. (2006) and the name was subsequently validly published in Validation List no. 114 (Masaki et al., 2007). Two further isolates were considered to belong to the species on the basis of *rpoB* sequence analysis, but showed some variation in phenotypic properties and in 16S rRNA gene and *hsp65* sequence analyses (Masaki et al., 2006).

43. **Mycobacterium hiberniae** Kazda, Cooney, Monaghan, Quinn, Stackebrandt, Dorsch, Daffé, Müller, Cook and Tarnok 1993, 355[VP]

hi.ber.ni′a.e. L. gen. n. *hiberniae* of *Hibernia*, the Latin name for Ireland, the source of the strains.

Acid–alcohol-fast, beaded rods (0.9 × 1.2–1.5 μm) which frequently form clumps, but not cords. Aerial hyphae, capsules, spores, and true branching do not occur. Smooth, compact, and glistening rose-pink colonies (1–1.5 mm in diameter) are formed on Löwenstein–Jensen medium and Middlebrook 7H10 agar after incubation for 20 d. Strains are eugonic in the first phase of growth, but later become dysgonic and assume a rough, dry appearance after longer incubation (8 weeks). Temperature range for growth is 22–37°C, optimal growth is at 37°C; does not grow at 42 or 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Cells provoke a non-specific hypersensitivity reaction to bovine tuberculin. The organism is not pathogenic for guinea pigs, mice, or rabbits.

Source: the original description is based on 13 strains isolated from moss, sphagnum vegetation, and soil collected in counties Clare and Donegal in Ireland.

DNA G+C content (mol%): not determined.

Type strain: ATCC 49874, CIP 104537, DSM 44241, JCM 13571.

Sequence accession no. (16S rRNA gene): X67096.

44. **Mycobacterium arupense** Cloud, Meyer, Pounder, Jost, Sweeney, Carroll and Woods 2006, 1417[VP]

a.rup.en′se. N.L. neut. adj. *arupense* pertaining to the ARUP Institute for Clinical and Experimental Pathology, where the type strain was characterized.

Acid-fast, non-chromogenic bacilli. The organism grows rapidly (5–7 d) on Löwenstein–Jensen medium at 30°C and slowly (10–12 d) at 37°C. It does not grow at 42°C on MacConkey agar lacking crystal violet or on media supplemented with 5% (w/v) NaCl. Differential characteristics of slowly growing species are shown in Table 37.

Source: the type strain was isolated from a human tendon. Additional strains have been obtained from bronchial washings, a finger wound, and sputum. Clinical significance may vary with site of isolation.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-1242, DSM 44942.

Sequence accession nos: DQ157760 (16S rRNA gene); DQ168662 (*hsp65*); DQ168663 (ITS).

Additional remarks: the 16S rRNA gene sequence of *Mycobacterium arupense* has a long helix 18 in the hyper-variable region V3, a feature seen in slow-growing *Mycobacterium* species. However, phenotypic assessment of the growth rate shows more rapid growth at lower temperature. Hence, this species is considered to have an intermediate growth rate.

45. **Mycobacterium nonchromogenicum** Tsukamura 1965, 110[AL]

non.chrom.o.gen′i.cum. L. adv. *non* not; Gr. n. *chroma* color; Gr. v. *gennaio* to produce; L. suff. *-icum* suffix used with the sense of pertaining to; N.L. neut. adj. *nonchromogenicum* intended to mean not producing color.

Gram-stain-positive, acid-fast, moderately long to long rods. Colonies on Löwenstein–Jensen medium and Middlebrook agar are smooth to rough and white to buff after incubation for 7 or more days at 37°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from mice injected with soil; bacilli persist in tissues of mice without evidence of pathogenicity (Tsukamura, 1967b). Usually appears in clinical specimens as an environmental contaminant. A few cases are documented in which *Mycobacterium nonchromogenicum* or *Mycobacterium terrae* have been considered as the cause of human disease (Wolinsky, 1979a).

DNA G+C content (mol%): not determined.

Type strain: ATCC 19530, CCUG 28009, CIP 106811, DSM 44164, JCM 6364, NCTC 10424.

Sequence accession no. (16S rRNA gene): M29565.

Additional remarks: in numerical taxonomic analyses, two clusters corresponding to *Mycobacterium nonchromogenicum* and *Mycobacterium terrae* are seen. However, these clusters link to one another at a higher similarity level than they do to other species (Meissner et al., 1974). Positive reactions for nicotinamidase and pyrazinamidase and negative nitrate reduction provide the most definitive means of distinguishing *Mycobacterium nonchromogenicum* from *Mycobacterium terrae*.

Dermal hypersensitivity testing shows a tenuous distinction between *Mycobacterium nonchromogenicum* and *Mycobacterium terrae* (Meissner et al., 1974), but immunodiffusion analysis does not permit their differentiation (Stanford and Grange, 1974). The overall similarities between *Mycobacterium nonchromogenicum*, *Mycobacterium terrae*, and *Mycobacterium triviale* raise questions about their status as separate species. Since all of them are generally considered clinically insignificant, it is common practice to identify such strains as members of the "*Mycobacterium terrae* complex" without further taxonomic resolution.

Single-membered 16S rRNA gene clades

46. **Mycobacterium leprae** (Hansen 1880) Lehmann and Neumann 1896, 372[AL] (*Bacillus leprae* Hansen 1880, 32)

le′pra.e. L. n. *lepra* leprosy; L. gen. n. *leprae* of leprosy.

Common name: Leprosy bacillus or Hansen's bacillus.

Strongly acid-fast rods (1.0–8.0 × 0.3–0.5 μm) with parallel sides and rounded ends which stain evenly or at times are beaded. When numerous, as from lepromatous cases, cells are generally arranged in clumps, rounded masses (globi) or in groups of bacilli aligned side by side. Fisher and Barksdale (1973) reported that bacilli in leprosy lesions were distinctive in losing their acid-fastness on extraction with pyridine. However, clinical specimens usually contain a high proportion of non-viable bacilli characterized by poor and uneven staining (McRae and Shepard, 1971). Hence, the pyridine effect may reflect either a species characteristic or merely the state of viability.

The organism has not been cultured in artificial media despite periodic claims to the contrary. Bacilli from human leprous tissue multiply with an apparent generation time of 20–30 d when inoculated into footpads of healthy mice (Shepard, 1960; Shepard and Chang, 1962). When corrected for the presence of "non-viable" (i.e. non-solid-staining) bacilli, generation times as low as 10 d are seen (Shepard and McRae, 1971). Generation times in mouse footpads appear to be strain-specific (Shepard and McRae, 1971). During *in vivo* cultivation in mice, the leprosy bacilli do not invade deep tissues and their multiplication can be inhibited by cycloserine, diaminodiphenyl sulfone, isoniazid, ρ-aminosalicylic acid, and rifampin. Experimental transmission to immunosuppressed mice and rats causes lepromatous-like model infections (Fieldsteel and McIntosh, 1971; Rees et al., 1967).

The discovery that *Mycobacterium leprae* can multiply extensively in tissues of the nine-banded armadillo (*Dasypus novemcinctus*) led to the use of this animal to produce large quantities of bacilli for subsequent study (Kirchheimer and Storrs, 1971). However, care must be taken to distinguish biological products of mycobacterial origin from those that may have been adsorbed onto the bacilli from host tissues.

Mycolic acids have been identified in *Mycobacterium leprae* and these resemble those of *Mycobacterium gordonae* more than those of any other *Mycobacterium* species (Daffé et al., 1981; Kusaka et al., 1981; Minnikin et al., 1985; Young, 1980). Little, if any, tuberculostearic acid is produced; in this regard, *Mycobacterium leprae* again resembles *Mycobacterium gordonae* (Asselineau, 1981). A phenolic glycolipid resembling mycoside A of *Mycobacterium kansasii* but bearing a different trisaccharide component has been isolated from *Mycobacterium leprae* (Hunter and Brennan, 1981).

Causes leprosy in man. In the lepromatous form of the disease, bacilli are so abundant in the tissue that they produce stuffed-cell granulomas; in tuberculoid and neural lesions, organisms are rare.

Source: obligate intracellular parasite; confined largely to the skin (especially to convex and exposed surfaces), testes, and to peripheral nerves. Probably does not grow in the internal organs.

DNA G+C content (mol%): 57.8 (whole-genome sequencing).

Type strain: not cultivated; none designated.

Sequence accession no. (16S rRNA gene): X53999.

Additional remarks: Stanford et al. (1975) detected 12 antigens in *Mycobacterium leprae* extracts by immunodiffusion and found that six were common to all mycobacteria and nocardiae tested with four appearing to be specific to *Mycobacterium leprae*. Sera from leprosy patients contain antibodies that react with antigens from a number of mycobacterial species by immunodiffusion and immunoelectrophoresis

analyses (Kronvall et al., 1976; Norlin et al., 1966). At least 20 distinct antigenic components have been detected in *Mycobacterium leprae* by immunoelectrophoresis (Closs et al., 1979), seven of which reacted with sera from lepromatous patients. Gillis and Buchanan (1982) found that out of 11 monoclonal antibodies raised against *Mycobacterium leprae* extracts only two reacted against *Mycobacterium leprae*; the others showed various patterns of reaction with the other 18 species tested. Brennan and Barrow (Brennan and Barrow, 1980) partially purified a lipid from *Mycobacterium leprae* which appeared to be analogous to the C-mycosidic peptidoglycolipids responsible for specific agglutination of the serovars of the *Mycobacterium avium* complex. This lipid is serologically active and may be specific for this *Mycobacterium leprae* strain. Heated suspensions of bacilli (obtained from nodules) produce a positive lepromin reactin in 75–97% of normal persons and of tuberculoid cases of leprosy, but usually do not produce a reaction in lepromatous individuals (Hayashi, 1932).

47. **Mycobacterium lepraemurium** Marchoux and Sorel 1912, 700[AL]

lep.rae.mu′ri.um. L. gen. n. *leprae* of leprosy; L. gen. pl. n. *murium* of mice; N.L. gen. pl. n. *lepraemurium* of leprosy of mice.

Strongly acid-fast rods (3–5 μm in length) with slightly rounded ends. Cells often show an irregular appearance when stained. Only the densely and uniformly stained forms appear to be infective for animals, in contrast to the "degenerate" unevenly stained forms (Rees et al., 1960). The bacilli from lesions are not bound together in clumps, rounded masses, or palisades as in human leprosy.

Following many years of unsuccessful attempts to grow this organism *in vitro*, Ogawa and Motomura (1970) succeeded by inoculating many cells onto an inspissated 1% egg yolk medium. This approach was used by Saito et al. (1976) to determine the biochemical and biological characteristics of *Mycobacterium lepraemurium* strain Keishicho. Dense compact inocula on Ogawa egg medium leads to the growth of rough, non-chromogenic colonies after incubation for 4–5 weeks at 30–37°C. Growth also occurs on agar-based media supplemented with cytochrome *c* and α-ketoglutaric acid. Slow growth has been recorded in an enriched Kirchner liquid medium, though this seems to be dependent upon the maintenance of reducing conditions (Dhople and Hanks, 1981). TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

A cause of endemic disease of rats in various parts of the world. The natural disease occurs chiefly in the lymph nodes and on skin, causing induration, alopecia, and eventual ulceration. Nodular diseases of the skin of other animals have been associated with similar acid-fast bacilli.

Source: a primary isolate has never been recorded.

DNA G+C content (mol%): not determined.

Type strain: non-specified due to difficulties in cultivation.

Sequence accession no. (16S rRNA gene): AJ279017.

Additional remarks: cell walls of *Mycobacterium lepraemurium* contain arabinose and galactose as principal cell-wall sugars, alanine, glutamic acid, and *meso*-diaminopimelic acid as mucopeptide amino acids, and a high proportion of lipid, which is typical of other, cultivable mycobacteria (Cummins et al., 1967). DNA from *Mycobacterium lepraemurium* shows a higher homology to that of *Mycobacterium avium* than to any other mycobacterial species (Imaeda et al., 1982). Using immunodiffusion analysis, Stanford (1973) revealed three antigens from *Mycobacterium lepraemurium* that were previously considered unique to *Mycobacterium avium*. Additionally, *Mycobacterium lepraemurium* produced two antigens that were not shared with any other mycobacterial species tested. The T-catalase of *Mycobacterium lepraemurium* occupies a unique position on the diagram of divergence of T-catalase lying between those of *Mycobacterium avium* and *Mycobacterium tuberculosis* (Katoch et al., 1982).

48. **Mycobacterium szulgai** Marks, Jenkins and Tsukamura 1972, 211[AL]

szul′gai. N.L. gen. masc. n. *szulgai* of Szulga, named after T. Szulga, a Polish microbiologist.

Acid-fast, moderately long rods with some patchy staining or cross-barring. Colonies on egg medium are usually smooth and easily emulsified following incubation for 2 weeks at 37°C, but rough forms may appear after prolonged subculture. The production of an orange pigment is enhanced by growth in continuous light. *Mycobacterium szulgai* is scotochromogenic when grown at 37°C, but at 25°C it tends to be photochromogenic (Schaefer et al., 1973). Growth is inhibited in media supplemented with 5% (w/v) NaCl. Strains exhibit specific agglutination with *Mycobacterium szulgai* antiserum and a unique TLC pattern of a surface lipid antigen (Marks et al., 1972; Schaefer et al., 1973). This antigen is of the alkali-labile type (Brennan, 1981). TLC of methanolysates shows α-, keto-, and methoxy-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from patients with cervical adenitis, olecranon bursitis, and pulmonary disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35799, CCUG 37675, CIP 104532, DSM 44166, JCM 6383, NCTC 10831.

Sequence accession no. (16S rRNA gene): X52926.

Additional remarks: in routine diagnostic clinical practice, *Mycobacterium szulgai* may be mistaken for *Mycobacterium flavescens*, nominally a rapid grower. Since, unlike *Mycobacterium szulgai*, *Mycobacterium flavescens* is not a pathogen, it is essential that appropriate tests be conducted to distinguish between them. In spite of superficial similarities, these species form distinct clusters in numerical taxonomic studies (Selva-Sutter et al., 1976; Wayne et al., 1981).

49. **Mycobacterium seoulense** Mun, Kim, Oh, Kim, Bai, Yu, Park, Cha, Kook and Kim 2007, 597[VP]

se.oul.en′se. N.L. neut. adj. *seoulense* of or pertaining to Seoul, Republic of Korea, the geographical origin of the type strain.

Acid–alcohol-fast, rod-shaped cells that are frequently bent and occasionally coccoid. Spores and filaments are not present. Micro-colonies may be visible in 2 weeks on Middlebrook 7H10 agar; smooth, orange-pigmented; mature

colonies require incubation for 3 weeks. Growth may be slower (4 or more weeks) on Löwenstein–Jensen medium and appear as an orange-colored surface film. Temperature range for growth is 25–37°C, optimal growth is at 37°C; does not grow at 45°C. Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated on three occasions from sputum samples of a 52-year-old female patient experiencing generalized pulmonary symptoms.

DNA G+C content (mol%): not determined.

Type strain: DSM 44998, KCTC 19146.

Sequence accession no. (16S rRNA gene): DQ536403.

50. **Mycobacterium scrofulaceum** Prissick and Masson 1956, 802[AL]

scro.fu.la′ce.um. L. pl. n. *scrofulae* a swelling of the glands of the neck, scrofula; L. neut. suff. *-aceum* suffix used with various meanings; N.L. neut. adj. *scrofulaceum* of or pertaining to scrofula.

Acid-fast, short to long rods or filaments. Colonies on Middlebrook medium and Löwenstein–Jensen medium are usually smooth and yellow to orange in color, but occasional strains may produce rough growth. Growth occurs in 7 or more days at 37°C. Temperature range for growth is 22–42°C; optimal growth is at 35°C. TLC of methanolysates shows α- and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Mycobacterium scrofulaceum does not cause extensive generalized disease in chickens, hamsters, or rats, but may produce some lymph node involvement and rarely localized lesions in the liver or spleen (Penso et al., 1957; Prissick and Masson, 1957). Subcutaneous inoculation of guinea pigs produces abscesses at the site of inoculation and enlargement of regional nodes. Intraperitoneal inoculation causes enlargement and suppuration of regional lymph nodes and, consistently, peritonitis of various degrees and, rarely, lesions of the liver or spleen, but not generalized disease or death (Penso et al., 1957; Prissick and Masson, 1957).

Source: isolated from a closed lesion of cervical lymphadenitis in a child (Prissick and Masson, 1956). Also found in pus from suppurating cervical lymph nodes, especially in children, and considered to be the etiologic agent of the lesions (Prissick and Masson, 1957). Although *Mycobacterium scrofulaceum* is still occasionally encountered in such conditions, it is now a less likely cause of lymphadenitis in children than other mycobacterial species, notably organisms of the *Mycobacterium avium* complex (Falkinham, 1996). *Mycobacterium scrofulaceum* is also found in human sputum and gastric lavage samples, and is occasionally associated with pulmonary disease (Wolinsky, 1979a). The species has been found in the environment (Kestle et al., 1967; Wolinsky and Rynearson, 1968) and in swine (Schaefer, 1968).

DNA G+C content (mol%): not determined.

Type strain: ATCC 19981, CCUG 29045, CIP 105416, DSM 43992, JCM 6381, NCTC 10803.

Sequence accession no. (16S rRNA gene): X52924.

Additional remarks: Mycobacterium scrofulaceum was conserved over the specific epithet *Mycobacterium marianum*, a senior subjective synonym, in Opinion 53 of the Judicial Commission. *Mycobacterium marianum* was placed on the list of *nomina rejicienda* because of its orthographic similarity to the valid epithet *Mycobacterium marinum* (Judicial Commission of the International Committee on Systematic Bacteriology, 1978).

Schaefer (1965, 1968) established three serovars within this species by seroagglutination. These correspond to TLC patterns seen with surface lipid antigens (Jenkins et al., 1972; Wayne et al., 1971) of the alkali-stable type (Brennan, 1981). A fourth serovar, designated 44 (Goslee et al., 1976), has since been redesignated *avium* complex serovar 27 (Wolinsky, 1979b). *Mycobacterium scrofulaceum* forms a distinct species on the basis of reciprocal dermal skin testing (Baess and Magnusson, 1982; Magnusson, 1962, 1980; Runyon and Dietz, 1971; Wayne et al., 1971), immunoelectrophoresis (Castelnuovo and Morellini, 1962), and immunodiffusion (Stanford and Grange, 1974).

Mycobacterium scrofulaceum is sometimes assigned to the so-called MAIS complex. The data from many taxonomic studies using several different procedures make it inappropriate to include this species in a complex with *Mycobacterium avium* and *Mycobacterium intracellulare* (see discussion under *Mycobacterium avium* subsp. *avium*).

51. **Mycobacterium conspicuum** Springer, Tortoli, Richter, Grünewald, Rüsch-Gerdes, Uschmann, Suter, Collins, Kroppenstedt and Böttger 1996a, 362[VP] (Effective publication: Springer, Tortoli, Richter, Grünewald, Rüsch-Gerdes, Uschmann, Suter, Collins, Kroppenstedt and Böttger 1995b, 2810.)

con.spi′cu.um. L. neut. adj. *conspicuum* in view, visible, apparent, obvious, referring to the unique profile of this species.

Acid–alcohol-fast coccobacilli. Does not form aerial hyphae, capsules, or spores. Visible growth occurs in 2–3 weeks from dilute inocula on Löwenstein–Jensen medium. Colonies are dysgonic, smooth, yellowish, and non-photochromogenic. Temperature range for growth is 22–31°C; does not grow at 37°C under routine conditions. However, growth at 37°C was achieved in BACTEC 12B medium. Does not grow on MacConkey agar or in the presence of 5% (w/v) NaCl. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from two patients with immune deficiency and disseminated mycobacterial infection.

DNA G+C content (mol%): not determined.

Type strain: DSM 44136, CIP 105165, ATCC 700090.

Sequence accession no. (16S rRNA gene): X88922.

52. **Mycobacterium lacus** Turenne, Chedore, Wolfe, Jamieson, Broukhanski, May and Kabani 2002a, 2138[VP]

la′cus. L. gen. n. *lacus* of the lake, where the organism was acquired.

Large, dispersed acid-fast bacilli with prominent beading. Neither aerial hyphae or spores are produced. Visible growth appears in 2 weeks at 37–42°C from dilute inocula, but requires 3–4 weeks at 25–30°C. Colonies on Löwenstein–Jensen medium are small, dry, and

non-chromogenic. Colonies on Middlebrook 7H10 agar are small, non-pigmented, and smooth to rough with a slightly irregular edge. Younger colonies appear slightly transparent. Temperature range for growth is 25–42°C, optimal growth at 37°C. Does not grow on MacConkey agar (without crystal violet) or in the presence of 5% (w/v) NaCl. Differential characteristics of slowly growing species are shown in Table 37.

Source: a single isolate was obtained from synovial tissue of a 68-year-old female patient with bursitis of the right elbow thought to be due to trauma whilst swimming in a lake.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-323, DSM 44577.

Sequence accession no. (16S rRNA gene): AF406783.

53. **Mycobacterium intermedium** Meier, Kirschner, Schröder, Wolters, Kroppenstedt and Böttger 1993, 207[VP]

in.ter.me′di.um. L. neut. adj. *intermedium* intermediate, referring to the phylogenetic position of this organism between the rapidly and slowly growing mycobacteria.

Acid–alcohol-fast coccobacilli (2.0 × 2.6 µm). Does not form aerial hyphae, capsules, or spores. Visible growth appears in 2–3 weeks from dilute inocula on Löwenstein–Jensen medium. Colonies are 3–5 mm in diameter, eugonic, smooth, and photochromogenic. Temperature range for growth is 22–41°C; optimal growth is between 31 and 37°C; does not grow at 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: three isolates were obtained from the sputum of a patient with pulmonary disease.

DNA G+C content (mol%): not determined.

Type strain: DSM 44049, ATCC 51848, CCUG 37583, CIP 104542, JCM 13572.

Sequence accession no. (16S rRNA gene): X67847.

54. **Mycobacterium cookii** Kazda, Stackebrandt, Smida, Minnikin, Daffé, Parlett and Pitulle 1990, 221[VP]

cook′i.i. N.L. gen. masc. n. *cookii* of Cook, named for Bertram Cook, who discovered the natural reservoir of this species.

Acid–alcohol-fast, polymorphic rods (0.8 × 1.4–1.9 µm) which often form clumps but not cords, nor is cross banding evident. Does not produce aerial hyphae, capsules, spores, or true branching. Colonies on Löwenstein–Jensen medium and Middlebrook 7H10 agar are 0.5–1.0 mm in diameter and smooth, glistening with yellow-orange scotochromogenic pigmentation. Visible growth from dilute inocula occurs after incubation for 4 weeks. Optimal temperature for growth is 31°C; many strains grow at 22°C, but growth does not occur at or above 37°C. The organism shows limited enzymic activity and does not grow on media containing single carbon sources or single sources of carbon plus nitrogen. TLC of methanolysates shows α- and α′-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

The strains were not pathogenic for guinea pigs, mice, or rabbits, but they did stimulate non-specific tuberculin reactions in sensitized guinea pigs and were regarded as a source of non-specific tuberculin reactions in cattle in some regions of New Zealand (Cook and Kazda, 1988; Kazda and Cook, 1987).

Source: seventeen strains were isolated from sphagnum vegetation and pond water collected from sites throughout the North and South Islands of New Zealand.

DNA G+C content (mol%): 63.7 ± 3 (T_m).

Type strain: ATCC 49103, CIP 105396, DSM 43922, JCM 12404.

Sequence accession no. (16S rRNA gene): X53896.

55. **Mycobacterium triviale** Kubica *in* Kubica, Silcox, Kilburn, Smithwick, Beam, Jones and Stottmeier 1970, 162[AL]

tri.vi.a′le. L. neut. adj. *triviale* common, commonplace, vulgar, ordinary, of little importance.

Acid-fast rods. From dilute inocula, mature colonies do not appear on solid media for over a week. Colonies on egg medium are rough, dry, heaped, and non-chromogenic. Characteristic rough R colonies are seen on oleic acid agar that are easily confused with those of *Mycobacterium tuberculosis*. Grows poorly, if at all, on cornmeal agar. *Mycobacterium triviale* shares many diagnostic features with *Mycobacterium nonchromogenicum* and *Mycobacterium terrae*, but differs from these taxa and from most other slow-growing mycobacteria in its consistent ability to grow in the presence of 5% (w/v) NaCl (Kubica et al., 1970). TLC of methanolysates shows α-mycolates. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from sputum, but is not considered to be a pathogen.

DNA G+C content (mol%): not determined.

Type strain: ATCC 23292, CCUG 42431, DSM 44153.

Sequence accession no. (16S rRNA gene): X88924.

56. **Mycobacterium tusciae** Tortoli, Kroppenstedt, Bartoloni, Caroli, Jan, Pawlowski and Emler 1999, 1843[VP]

tus.ci′a.e. L. gen. n. *tusciae* of *Tuscia*, now Tuscany, the Italian region where all the organisms were isolated.

Acid–alcohol-fast, nonmotile, non-spore forming rods. Colonial growth occurs in 4 weeks on Löwenstein–Jensen medium at temperatures from 25 to 32°C. At 37°C, growth on Löwenstein–Jensen is inconsistent and scanty, but is better on Middlebrook 7H11 agar and in Bactec 12B liquid medium. Colonies are rough and scotochromogenic with an elevated center surrounded by a flat and uneven fringe. Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from a lymph node of an immunocompromised child. Additional isolates have been obtained from tap water and from a respiratory sample from a patient with chronic fibrosis; however, the organism is not to be considered to be a pathogen.

DNA G+C content (mol%): 66.4 (HPLC).

Sequence accession no. (16S rRNA gene): AF058299.

Additional remarks: although this organism displays slow growth it appears to cluster near to the rapidly growing species in the phylogeny shown in Figure 86.

57. **Mycobacterium shimoidei** Tsukamura 1982, 67[VP]

shi.moid′e.i. N.L. gen. masc. n. *shimoidei* of Shimoide, named for H. Shimoide, a Japanese microbiologist who first isolated a strain of this species.

Acid-fast rods (3–5 × 0.6 µm) with frequent cross barring, but does not exhibit cord formation or a mycelium. Rough, non-pigmented colonies appear after incubation for 14–21 d on Löwenstein–Jensen medium. Does not grow on media supplemented with 5% (w/v) NaCl. Temperature range for growth is 28–45°C; optimal growth is at 37–45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates, and wax esters. Differential characteristics of slowly growing species are shown in Table 37.

Source: isolated from sputum and considered to be a cause of pulmonary disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27962, CCUG 37517, DSM 44152, JCM 12376.

Sequence accession no. (16S rRNA gene): AJ005005.

Additional remarks: the four cultures upon which the original description of this species was based were isolated from the same patient in Japan (Tsukamura, 1982). However, another culture exhibiting similar properties was isolated from a patient in Australia. All of the strains differed markedly from those of other known species on the basis of numerical taxonomic data (Wayne et al., 1971).

List of rapid-growing species of the genus *Mycobacterium*

Multimembered 16S rRNA gene clades

The *Mycobacterium chitae* clade

58. **Mycobacterium chitae** Tsukamura 1967a, 44[AL]

chi′ta.e. N.L. gen. n. *chitae* of Chita, a place in Japan.

Acid-fast, coccoid-like elements, which do not show branching, cord, or mycelium formation. Acid-fastness is strong in younger cultures, but may become partial in older cultures (Wayne and Kubica, 1986). White or cream colored, smooth, wet-looking, non-pigmented colonies are formed on most media after 3–5 d following the addition of dilute inocula. The temperature range for growth is 28–37°C; does not grow at 45°C. *Mycobacterium chitae* is tolerant to 5% (w/v) NaCl, but does not grow on MacConkey agar (without crystal violet). TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Virulence studies revealed *Mycobacterium chitae* to be avirulent for chickens, guinea pigs, mice, and rabbits injected with 2–10 mg of the organism. Not known to be associated with human disease.

Source: four strains of this species were originally isolated from soil samples collected from manure heaps.

DNA G+C content (mol%): not determined.

Type strain: ATCC 19627, CCUG 39504, CIP 105383, DSM 44633, JCM 12403, NCTC 10485.

Sequence accession no. (16S rRNA gene): X55603.

Additional remarks: initially described in Japanese (Tsukamura, 1966c), and later in English (Tsukamura, 1967a).

59. **Mycobacterium fallax** Lévy-Frébault, Rafidinarivo, Promé, Grandry, Boisvert and David 1983, 342[VP]

fal′lax. L. neut. adj. *fallax* deceptive, in the sense that the colonies resemble those of *Mycobacterium tuberculosis*.

Acid-fast, short rods (0.5 × 1.0 µm long), except for a small number (less than 20%) of cyanophil forms. Smears prepared from Youman's medium (without Tween 80) show clumps of rods or cords. Growth occurs within 5 d at 30°C on Löwenstein–Jensen, Middlebrook 7H10, and nutrient agar media. Larger colonies are produced by incubation at 37°C, but colonies grow more slowly (12–21 d or more); significant numbers of isolates fail to grow on nutrient agar at this temperature. At both temperatures, colonies are eugonic, rough, and buff-colored, and resemble those of *Mycobacterium tuberculosis*. Cord formation is evident at the edges of colonies on Middlebrook 7H10 medium. In addition to colonial characteristics, this organism shares nitrate reductase production and thermolabile catalase activity with *Mycobacterium tuberculosis*, but differs from the latter as it is niacin-negative and grows rapidly at 30°C. TLC of methanolysates shows α-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: all but three of the initial 22 strains were isolated from river and lake water. The remaining three strains were isolated from sputum though this organism is not known to be a cause of disease.

DNA G+C content (mol%): not determined.

Type strain: CIP 81.39, ATCC 35219, CCUG 37584, DSM 44179, JCM 6405.

Sequence accession no. (16S rRNA gene): M29562.

The *Mycobacterium komossense* clade

60. **Mycobacterium komossense** Kazda and Müller 1979, 364[AL]

ko.mos.sen′se. N.L. neut. adj. *komossense* of or belonging to Komosse sphagnum bog in south Sweden.

Short to moderately long rods, often clumped, but never corded or cross-barred. Dilute inocula on both inspissated egg and oleic acid-albumin media yield eugonic, smooth, glistening, yellow-beige, scotochromogenic colonies in less than 7 d. Temperature range for growth is 22–37°C, with optimal growth at 31°C; does not grow at 45°C. TLC of methanolysates shows α-, keto-, and methoxy-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Injection of guinea pigs, mice, and rabbits with large inocula (1–10 mg wet weight of cells) produced neither local nor disseminated disease.

Source: isolated from sphagnum vegetation of intact sphagnum bogs in southern Sweden and the Atlantic coastal area of Norway; not recovered from partially cultivated moors.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33013, CIP 105293, DSM 44078.

Sequence accession no. (16S rRNA gene): X55591.

61. **Mycobacterium aichiense** Tsukamura, Mizuno and Tsukamura 1981, 274[VP]

ai.chi.en′se. N.L. neut. adj. *aichiense* of or belonging to Aichi prefecture, Japan.

Rods, less than 2 μm in length. Acid-fast in young cultures, but may lose some acid-fastness on prolonged culture. Dilute inocula on egg and agar media yield yellow-orange, smooth colonies in 3–4 d or less. The temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from soil and from sputum of humans but is not associated with disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27280, CIP 106808, DSM 44147, JCM 6376, NCTC 10820.

Sequence accession no. (16S rRNA gene): X55598.

Additional remarks: this species was originally described in Japanese (Tsukamura, 1973) and was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), but was revived by Tsukamura et al. (1981).

62. **Mycobacterium holsaticum** Richter, Niemann, Gloeckner, Pfyffer and Rüsch-Gerdes 2002, 1995[VP]

hol.sa′ti.cum. M.L. neut. adj. *holsaticum* of or belonging to *Holsatia*, the German region of Holstein, the location of the institute in which the strains were first analyzed.

Acid–alcohol-fast rods and cocci. Colony morphology is dependent on the temperature of incubation; colonies are dysgonic and transparent at 22°C, but smooth, moist, shiny, and off-white- to yellow-pigmented at higher temperatures. Growth occurs in 7 d within the temperature range 22–40°C. Strains tolerate 5% (w/v) NaCl, but do not grow on MacConkey agar. TLC of methanolysates shows α-, keto-, and methoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: nine strains were isolated from a variety of clinical specimens from different patients in various regions of Germany; the species is of doubtful pathogenicity for humans.

DNA G+C content (mol%): 68.4 (HPLC).

Type strain: DSM 44478, CCUG 46266, JCM 12374.

Sequence accession nos: AJ310467 (16S rRNA gene); AJ310468 (16S–23S rRNA ITS); AJ310469 (*hsp65*).

63. **Mycobacterium murale** Vuorio, Andersson, Rainey, Kroppenstedt, Kämpfer, Busse, Viljanen and Salkinja-Salonen 1999, 34[VP]

mu.ra′le. L. neut. adj. *murale* of or belonging to a wall.

Acid–alcohol-fast rods or coccoid cells (0.6–1.4 × 0.4–0.5 μm). Growth occurs as smooth, saffron yellow, scotochromogenic colonies within 5 d on tryptone soya blood agar. Does not grow on MacConkey agar (without crystal violet) or on 5% (w/v) NaCl agar. The temperature range for growth is 10–37°C, with optimal growth at 30°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: five strains were isolated from water-damaged indoor building material in Finland, mycobacteria were not found in non-water damaged parts of the same building materials (Andersson et al., 1997).

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: DSM 44340, CCUG 39728, CIP 105980, JCM 13392.

Sequence accession no. (16S rRNA gene): AB537171.

64. **Mycobacterium tokaiense** Tsukamura, Mizuno and Tsukamura 1981, 274[VP]

to.kai.en′se. N.L. neut. adj. *tokaiense* of or belonging to Tokai district of Japan.

Rods (1–7 μm long) which are sometimes cross-barred. Acid-fast in young cultures but may lose acid-fastness on prolonged incubation. Dilute inocula on egg media yield smooth, scotochromogenic colonies in less than 5 d. The temperature range for growth is 25–37°C, does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27282, CIP 106807, DSM 44635, JCM 6373, NCTC 10821.

Sequence accession no. (16S rRNA gene): AF480590.

Additional remarks: this species was initially described in Japanese (Tsukamura, 1973), was not cited on the *Approved Lists of Bacterial Names* (Skerman et al., 1980), and was revived by Tsukamura et al. (1981).

The *Mycobacterium austroafricanum* clade

65. **Mycobacterium austroafricanum** Tsukamura, van der Meulen and Grabow 1983c, 467[VP]

aus.tro.a.fri.ca′num. L. adj. *australis* southern; L. adj. *africanus -a -um* pertaining to Africa; N.L. neut. adj. *austroafricanum* of or pertaining to South Africa, the source of the isolates.

Acid-fast rods (2–6 × 0.5 μm). Growth occurs within 3 d at 28 and 37°C, but not at 42°C. Colonies are mucoid, yellowish in the dark, with pigment intensifying after exposure to light. The organism is susceptible to ethambutol (5 μg/ml), isoniazid (10 μg/ml), and $NH_2OH.HCl$ (250 μg/ml), but is resistant to rifampin (25 μg/ml) and thiophene-2-carboxylic acid hydrazide (1 μg/ml). Grows in the presence of 5% (w/v) NaCl. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: all strains were recovered from South African waters and are not known to be associated with human disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33464, CCUG 37667, CIP 105395, DSM 44191, JCM 6369.

Sequence accession no. (16S rRNA gene): X93182.

66. **Mycobacterium vanbaalenii** Khan, Kim, Paine and Cerniglia 2002, 2001[VP]

van.ba.a.len′i.i. N.L. gen. masc. n. *vanbaalenii* of Van Baalen, in memory of Chase Van Baalen (1925–1986), a professor at The University of Texas Marine Science Institute, Port Aransas Marine Laboratory, Port Aransas, Texas, USA.

Gram-stain-positive, acid-fast rods (1.4 × 0.7 µm). Colonies are smooth and scotochromogenic with a saffron yellow pigment on Middlebrook 7H10 medium. Grows well on brain heart infusion, trypticase soy, tryptone-yeast extract, and minimal balanced salt media. Pyrene, a polycyclic aromatic hydrocarbon, is degraded. The temperature range for growth is 24–37°C; at best, minimal growth is seen at 42°C; does not grow at 45°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from sediments in an oil-contaminated site in Redfish Bay, Texas, USA (Heitkamp et al., 1988).

DNA G+C content (mol%): 67.8 (whole-genome sequencing).

Type strain: DSM 7251, JCM 13017.

Sequence accession no. (16S rRNA gene): X84977.

Additional remarks: this species is closely related phylogenetically to *Mycobacterium austroafricanum*; the two type strains share a 16S rRNA gene sequence similarity value of 99.8%. However, in dot-blot DNA–DNA hybridization studies, the organisms showed less than 40% hybridization (Khan et al., 2002).

67. **Mycobacterium vaccae** Bönicke and Juhasz 1964, 133[AL]

vac′ca.e. L. n. *vacca* a cow; L. gen. n. *vaccae* of the cow.

Short acid-fast rods (1–4 × 0.5–0.8 µm) which may be curved with rounded or thickened ends; occasionally Y-shaped cells are seen. Acid-fastness is irregular in old cultures. Dilute inocula on Löwenstein–Jensen medium yield smooth, moist, yellow-orange, shiny, butyrous, domed colonies in less than 5 d. Most strains are very light sensitive; they are non-pigmented if grown in complete darkness, but become yellow after brief (minutes) exposure to light. Occasionally, rough or non-pigmented colonies are observed. The temperature range for growth is nominally 17–42°C, but growth is restricted and pigmentation is inhibited at 17 and 42°C; does not grow at 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from the lacteal glands and skin lesions of cattle and also from soil, watering ponds, and wells.

DNA G+C content (mol%): not determined.

Type strain: ATCC 15483, CCUG 21003, CIP 105934, DSM 43292, JCM 6389, NCTC 10916.

Sequence accession no. (16S rRNA gene): X55601.

Additional remarks: DNA–DNA relatedness studies (Baess, 1982) confirmed this as a distinct species and resolved some of the conflict in earlier international cooperative studies (Kubica et al., 1972; Saito et al., 1977).

68. **Mycobacterium aurum** Tsukamura 1966d, 266[AL]

au′rum. L. n. *aurum* gold, the color of gold, intended to mean gold-pigmented.

Acid-fast rods (1–6 µm in length). Smooth, yellow-orange colonies appear in less than 5 d on inspissated egg media. The temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters; some strains contain α′-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: strains isolated from soil may occasionally be seen in sputum in humans, but they do not cause disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 23366, CCUG 37666, CIP 104465, DSM 43999, JCM 6366.

Sequence accession no. (16S rRNA gene): X55595.

Additional remarks: the species was originally described in Japanese (Tsukamura and Tsukamura, 1966) and was first thought to be a variety of *Mycobacterium parafortuitum*; however, it could be differentiated from this taxon principally on the basis of growth temperature and pigmentation (Tsukamura, 1966a).

69. **Mycobacterium pyrenivorans** Derz, Klinner, Schuphan, Stackebrandt and Kroppenstedt 2004, 2316[VP]

py.re.ni.vo′rans. N.L. n. *pyrenum* pyrene; L. part. adj. *vorans* devouring, destroying; N.L. part. adj. *pyrenivorans* destroying pyrene.

Acid-fast rods. Rough, yellow scotochromogenic colonies are formed within 7 d at 35°C. Colonial pigmentation intensifies after exposure to light. In liquid media, cells clump together or show biofilm formation on glass. The temperature range for growth is 24–37°C; does not grow at 42 or 45°C. TLC of methanolysates shows α- and epoxy-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the type strain was isolated from soil that was highly contaminated with polycyclic aromatic hydrocarbons on the site of a former coking plant in Germany. It is named for its ability to use pyrene as a sole source of carbon and energy.

DNA G+C content (mol%): not determined.

Type strain: DSM 44605, NRRL B-24349.

Sequence accession no. (16S rRNA gene): AJ431371.

The *Mycobacterium doricum* clade

70. **Mycobacterium doricum** Tortoli, Piersimoni, Kroppenstedt, Montoya-Burgos, Reischl, Giacometti and Emler 2001, 2011[VP]

do′ri.cum. L. neut. adj. *doricum* of or belonging to *Dorica civitas*, the ancient name of the Italian city of Ancona, from where the organism was first isolated.

Acid–alcohol-fast, nonmotile, asporogenous rods. Colonies on Löwenstein–Jensen medium are smooth, scotochromogenic, and strongly yellow-pigmented. Growth occurs within 2 weeks at 25–37°C. Does not grow at 45°C, on MacConkey agar (without crystal violet), or on media supplemented with 5% (w/v) NaCl. TLC of methanolysates shows α- and methoxy-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from cerebrospinal fluid of a severely immunocompromised AIDS patient who was being treated for *Cryptococcus neoformans* infection.

DNA G+C content (mol%): 66.5 (HPLC).

Type strain: DSM 44339, CCUG 46352, CIP 106867, JCM 12405.

Sequence accession no. (16S rRNA gene): AF264700.

Additional remarks: Tortoli et al. (2001) describe strains as having α- and keto-mycolates, but Tortoli (2003) found the mycolate pattern to be α- and methoxy-mycolates, and wax esters; this latter finding was supported by Reischl et al. (2006) who used the mycolates pattern cited above to resolve the phenotypic similarities found between *Mycobacterium doricum* and *Mycobacterium monacense.* Despite slow growth on artificial media, the 16S rRNA gene nucleotide sequence of *Mycobacterium doricum* is characterized by a short helix 18, a feature usually associated with rapidly growing mycobacteria. Devulder et al. (2005) placed *Mycobacterium doricum* amongst rapidly growing species following 16S rRNA gene, *hsp65*, *rpoB*, and *sod* gene sequencing studies. Reischl et al. (2006) found that the 16S rRNA gene sequences of *Mycobacterium doricum* and *Mycobacterium monacense* differed by 14 bp, but recovered both taxa with rapidly growing species.

71. **Mycobacterium monacense** Reischl, Melzl, Kroppenstedt, Miethke, Naumann, Mariottini, Mazzarelli and Tortoli 2006, 2578[VP]

mo.na.cen′se. M.L. neut. adj. *monacense* of or pertaining to *Monacum*, the Latin name of the German city of Munich where the strain was first isolated.

Gram-stain-positive, acid-fast, asporogenous, nonmotile rods. Smooth, yellow, scotochromogenic colonies are produced within 7 d of incubation. Temperature for growth is 25–45°C; optimal growth is between 25–37°C. Grows on Löwenstein–Jensen medium supplemented with 5% (w/v) NaCl, but not on MacConkey medium (without crystal violet). TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: initially isolated from a bronchial lavage sample obtained from an 80-year-old patient with carcinoma. The species is of uncertain clinical significance, but one strain was isolated from a biopsy sample taken from a penetrating wound in an 11-year-old boy.

DNA G+C content (mol%): not determined.

Type strain: DSM 44395, CIP 109237.

Sequence accession nos: AF107039 (16S rRNA gene); DQ473393 (16S–23S rRNA ITS).

Additional remarks: the close relationship between *Mycobacterium monacense* and *Mycobacterium doricum* was borne out by comparative sequencing studies on the *hsp65* gene. See also comments following the description of *Mycobacterium doricum.*

The *Mycobacterium flavescens* clade

72. **Mycobacterium flavescens** Bojalil, Cerbón and Trujillo 1962, 344[AL]

fla.ves′cens. L. v. *flavesco* to become golden yellow; L. part. adj. *flavescens* becoming yellow.

Rod-shaped organism. Dilute inocula on Löwenstein–Jensen medium usually produce soft, yellow-orange, butyrous colonies after incubation for 7–10 d at 25–37°C; the colonies may adhere to the medium. The temperature range for growth is 25–42°C; does not grow at 45°C. Metabolic and physiological properties are more like those of rapidly growing species, even though the growth rate is intermediate between rapid and slow growers. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from drug-treated tuberculous guinea pig; other isolations as apparent normal flora of humans suggest an environmental habitat.

DNA G+C content (mol%): not determined.

Type strain: ATCC 14474, CCUG 29041, CIP 104533, DSM 43991, JCM 12274, NCTC 10271.

Sequence accession no. (16S rRNA gene): X52932.

73. **Mycobacterium novocastrense** Shojaei, Goodfellow, Magee, Freeman, Gould and Brignall 1997, 1206[VP]

no.vo.cas.tren′se. L. adj. *novus* new; L. neut. n. *castrum* castle; N.L. neut. adj. *novocastrense* of or pertaining to Newcastle, a city in the northeast of England.

Gram-stain-positive, asporogenous, nonmotile, weakly acid–alcohol-fast rods (3–4 μm long) with some longer rods and filamentous forms in older cultures. Dilute inocula on Löwenstein–Jensen medium and Middlebrook 7H10 agar produce moderately photochromogenic, yellow-pigmented growth when incubated for 3–7 d in the light at 30–42°C. Older cultures show a deeper yellow pigmentation. Good growth occurs on Columbia blood agar (3 d); weak growth is formed on MacConkey agar (without crystal violet) and 5% (w/v) NaCl agar after 14 d. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a slowly spreading skin granulation of the hand of a child.

DNA G+C content (mol%): not determined.

Type strain: DSM 44203, CIP 105546.

Sequence accession no. (16S rRNA gene): U96747.

Additional remarks: in clinical settings, it is possible that *Mycobacterium novocastrense* might be confused with *Mycobacterium marinum*, another photochromogenic organism which causes self-limiting granulomatous skin lesions. However, the two organisms can be distinguished readily as only *Mycobacterium novocastrense* reduces nitrate and grows at 42°C.

74. **Mycobacterium duvalii** Stanford and Gunthorpe 1971, 637[AL]

du.va′li.i. N.L. gen. masc. n. *duvalii* of Duval, named for Professor C.W. Duval who isolated two strains of the organism.

Pleomorphic bacilli producing rough or smooth, bright yellow colonies in less than 7 d on inspissated egg media at 25–37°C, but not at 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates, and wax esters. Serological specificity was demonstrated by immunodiffusion (Stanford and Gunthorpe, 1971) and by numerical taxonomic

data (Tsukamura et al., 1981). Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the four original strains were isolated from cases of human leprosy. However, the species has not been incriminated as a human or animal pathogen.

DNA G+C content (mol%): not determined.

Type strain: ATCC 43910, CCUG 41352, CIP 104539, DSM 44244, JCM 6396, NCTC 358.

Sequence accession no. (16S rRNA gene): U94745.

The *Mycobacterium agri* clade

75. **Mycobacterium agri** Tsukamura 1981, 256[VP]

ag′ri. L. gen. n. *agri* of a field.

Acid-fast rods (3–7 μm long) which frequently join to form long threads; does not form a mycelium or show cord formation. Colonies are rough and non-pigmented, both in the dark and after exposure to light, when grown for less than 5 d on egg media. The temperature range for growth is 28–45°C; does not grow at 52°C. TLC of methanolysates shows α-, α′-, and methoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the original isolate was recovered from an alkali-treated soil sample inoculated onto egg medium and incubated at 42°C. *Mycobacterium agri* is not known to be associated with disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27406, CCUG 37673 A, CIP 105391, DSM 44515, JCM 6377.

Sequence accession no. (16S rRNA gene): AJ429045.

Additional remarks: the organism was originally described by Tsukamura (1972b) but was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980); the epithet was revived by Tsukamura (1981).

76. **Mycobacterium thermoresistibile** Tsukamura 1966b, 266[AL]

ther.mo.re.sis.ti′bi.le. Gr. n. *thermê* heat; L. verb. *resisto* to stand back, remain standing, endure; L. neut. suff. *-ile* suffix denoting an active quality, able to; N.L. neut. adj. *thermoresistibile* resistant to high temperature.

Acid-fast rods (3–6 μm long). On primary isolation, growth may be slow and the species may be confused with slowly growing scotochromogens. However, subculture on inspissated egg media yields smooth or rough, yellow colonies in 3–5 d. The temperature range for growth is 37–52°C. *Mycobacterium thermoresistibile* lacks many properties common to rapidly growing mycobacteria such as growth on fumarate, malate, mannose, or succinate as sole carbon sources, and gives a negative aryl sulfatase reaction. TLC of methanolysates shows α-, α′-, methoxy, and keto-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolates have been recovered from soil and may occasionally be found in sputum samples from humans, but the organism is not known to be pathogenic.

DNA G+C content (mol%): not determined.

Type strain: ATCC 19527, CCUG 28008/41353, CIP 105390, DSM 44167, JCM 6362.

Sequence accession no. (16S rRNA gene): X55602.

Additional remarks: this organism was casually mentioned by Tsukamura (1965, in Japanese), then the name was validly published by Tsukamura (1966d) in English and by Tsukamura (1966b) in Japanese. The species was further described by Tsukamura (1971), with more definitive features presented by Tsukamura et al. (1981).

The *Mycobacterium smegmatis* clade

77. **Mycobacterium smegmatis** (Trevisan 1889) Lehmann and Neumann 1899, 403[AL] (*Bacillus smegmatis* Trevisan 1889, 14)

smeg.ma′tis. L. n. *smegma -atis* an unguent (for making the skin smooth), a detergent, a cleansing medicine, and in biology the sebaceous humor; L. gen. n. *smegmatis* of smegma.

Acid-fast rods (3–5 μm long), occasionally curved with branching or Y-shaped cells. Cells are sometimes swollen and may appear as deeper staining beaded or ovoid forms. Acid-fastness is irregular after incubation for 5 d (10–80%). Colonies that appear on Löwenstein–Jensen medium in 2–4 d are usually rough, wrinkled or coarsely folded, and non-pigmented or creamy white. Smooth, glistening, butyrous colonies are seen, but pigmentation is rare, though it may be seen in older cultures. On Middlebrook agar, the rough colonial form appears smooth textured over a rugose, but non-corded, granular colony; the smooth form is domed, smooth textured, and granular (Jones and Kubica, 1965). Temperature range for growth is 25–45°C. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Not pathogenic for chickens, guinea pigs, hamsters, or mice, but pathogenic cultures may be obtained from the spleens of guinea pigs and/or mice (Durr et al., 1959). *Mycobacterium smegmatis* is usually associated with secretions of the normal genitalia and with soft lesions following accidental or surgical trauma (Wallace et al., 1988).

Source: isolated from smegma tissue.

DNA G+C content (mol%): 67.4 (whole-genome sequencing).

Type strain: ATCC 19420, CCUG 21002/21815, CIP 104444, DSM 43756, JCM 5866/6386, NCTC 8159.

Sequence accession no. (16S rRNA gene): AJ131761.

Additional remarks: Mycobacterium smegmatis was named by Trevisan (1889) for the Smegma Bacillus of Alvarez and Tavel (1885) and was redescribed by Lehmann and Neumann (1899). Gordon and Mimh (1959) showed the taxon to be a good species, a conclusion supported by other workers (Baess, 1982; Kubica et al., 1972; Tsukamura, 1966d). Members of the species formed homogeneous groups based on species-specific sensitins (Magnusson, 1962), and immunodiffusion and immunological techniques (Castelnuovo et al., 1960; Gimpl and Lanyi, 1965; Lind, 1960; Norlin, 1965).

78. **Mycobacterium goodii** Brown, Springer, Steingrube, Wilson, Pfyffer, Garcia, Menendez, Rodriguez-Salgado, Jost, Chiu, Onyi, Böttger and Wallace 1999, 1509[VP]

go.od′i.i. N.L. gen. masc. n. *goodii* of Good, named for Robert Good who made significant contributions to the study of mycobacteria.

Acid- and alcohol-fast bacilli that produce smooth to mucoid off-white- to cream-colored colonies after incubation for 2–4 d on Middlebrook 7H10 and trypticase soy

agars. Yellow to orange pigment is produced by 78% of isolates after incubation for 10–14 d. Temperature range for growth is 30–45°C. Growth occurs on MacConkey agar (without crystal violet) and in the presence of 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Many of the 28 strains investigated were considered to be the causative agents of osteomyelitis or of respiratory infections.

Source: the type strain was isolated from a patient with a post-traumatic osteomyelitis of the heel.

DNA G+C content (mol%): 66 (HPLC).

Type strain: ATCC 700504, CIP 106349, DSM 44492, JCM 12689.

Sequence accession no. (16S rRNA gene): Y12872.

Additional remarks: this species was identified in a cooperative IWGMT study designed to determine the heterogeneity within the species *Mycobacterium smegmatis* (Brown et al., 1999). *Mycobacterium goodii* was previously known as *Mycobacterium smegmatis* Group 2. As with *Mycobacterium smegmatis* and strains of the *Mycobacterium fortuitum* complex, *Mycobacterium goodii* and *Mycobacterium wolinskyi* (see below) have been implicated in post-traumatic wound infections.

The *Mycobacterium phlei* clade

79. **Mycobacterium phlei** Lehmann and Neumann 1899, 411[AL]

phle′i. N.L. neut. n. *Phleum* a genus of grass, timothy; N.L. gen. n. *phlei* of *Phleum*, of timothy.

Short rods (1.0–2.0 µm long), acid-fast in young cultures, but staining irregularly after incubation for 5–7 d (5–100% acid-fast). Colonies are usually rough, coarsely wrinkled, and deep yellow- to orange-colored after incubation for 2–5 d on Löwenstein–Jensen medium. Smooth, butyrous colonial forms are occasionally seen. The rough colonial form on Middlebrook agar is flat, granular, loosely corded with irregular edges, and has dark granules near the center (Jones and Kubica, 1965). Temperature range for growth is 22–52°C; only *Mycobacterium phlei* and *Mycobacterium thermoresistibile* are known to grow at 52°C and both remain viable after heating at 60°C for 4 h. *Mycobacterium phlei* is tolerant of 5% (w/v) NaCl, but does not grow on MacConkey agar. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: once widely distributed in nature, especially hay and grass, but now rarely seen in environmental surveys (Wolinsky and Rynearson, 1968). Not pathogenic for carp, chicken, frog, guinea pig, mouse, rabbit, or rat (Durr et al., 1959; Penso et al., 1951).

DNA G+C content (mol%): not determined.

Type strain: ATCC 11758, CCUG 21000, CIP 105389, DSM 43239, JCM 5865/6385, NCTC 8151.

Sequence accession no. (16S rRNA gene): M29566.

Additional remarks: Mycobacterium phlei was proposed for the Timothy or Grass *Bacillus* of Moëller (1898). The taxon has been shown to be a good species using immunofluorescence (Jones and Kubica, 1968), species-specific sensitin (Magnusson, 1962), immunodiffusion and immunoelectrophoretic relatedness (Castelnuovo et al., 1960; Gimpl and Lanyi, 1965; Lind, 1960; Norlin, 1965), and DNA–DNA relatedness data (Baess, 1982).

80. **Mycobacterium brumae** Luquin, Ausina, Lévy-Frébault, Lanéelle, Belda, García-Barceló, Prats and Daffé 1993, 411[VP]

bru′ma.e. L. gen. n. *brumae* of winter, referring to the time of year at which the first strains were isolated.

Rods (2–2.5 × 0.3–0.5 µm). Most cells are strongly acid-fast but a few (less than 10%) show cyanophil forms. Clumping or cord formation may be observed on Middlebrook 7H12 medium. Colonies on Löwenstein–Jensen and on Middlebrook 7H12 agar are eugenic, rough, and non-pigmented in the dark and after exposure to light. Growth occurs within 5 d at 30 and 37°C, but not at 45°C. Growth does not occur on MacConkey agar (without crystal violet). TLC of methanolysates shows α-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: initially, 11 strains were isolated; eight were from samples of river water, two were from soil, and one was from a sputum sample.

DNA G+C content (mol%): not determined.

Type strain: CIP 103465, ATCC 51384, CCUG 37586, DSM 44177, JCM 12273.

Sequence accession no. (16S rRNA gene): AF480576.

81. **Mycobacterium confluentis** Kirschner, Teske, Schröder, Kroppenstedt, Wolters and Böttger 1992, 261[VP]

con.flu.en′tis. M.L. gen. n. *confluentis* of *Confluentes*, now Koblenz, the source of the strain on which the species description is based.

Acid–alcohol-fast cocco-bacilli (0.5–0.8 × 0.7–1.7 µm). Does not form aerial hyphae, capsules, or spores. Visible growth from dilute inocula occurs within 2–4 d. Colonies on Löwenstein–Jensen medium are colorless, smooth, and 3–5 mm in diameter. A dark pigmentation, not dependent on light, may be observed after prolonged culture (8–12 weeks). The temperature range for growth is 22–41°C; the optimal temperature is 31–37°C. Does not grow at 42 or 45°C. TLC of methanolysates shows α- and keto-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: a single isolate was obtained from the sputum of a healthy male.

DNA G+C content (mol%): not determined.

Type strain: DSM 44017, ATCC 49920, CIP 105510, JCM 13671.

Sequence accession no. (16S rRNA gene): X63608.

82. **Mycobacterium elephantis** Shojaei, Magee, Freeman, Yates, Horadagoda and Goodfellow 2000, 1819[VP]

e.le.phan′tis. L. n. *elephas -antis* elephant; L. gen. n. *elephantis* of the elephant.

Gram-stain-positive, aerobic, asporogenous, nonmotile, weakly acid–alcohol-fast cocco-bacilli (1.2–1.4 µm long). Colonies are smooth, domed, and non-chromogenic, although weak chromogenicity may appear in older cultures. The organism tolerates 5% (w/v) NaCl, but does not grow on MacConkey agar (without crystal violet). Good growth occurs within 7 d on Löwenstein–Jensen medium

and Middlebrook 7H10 agar at 25–45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a lung abscess of an elephant that had died from chronic respiratory disease. Subsequently, isolates were obtained from human clinical samples, predominantly sputum (Turenne et al., 2002b) though pathogenicity for humans remains doubtful. However, a case of lymph node infection appears to be clinically significant (Turenne et al., 2002b).

DNA G+C content (mol%): not determined.

Type strain: DSM 44368, CIP 106831, JCM 12406.

Sequence accession no. (16S rRNA gene): AJ010747.

83. **Mycobacterium pulveris** Tsukamura, Mizuno and Toyama 1983a, 811[VP]

pul've.ris. L. gen. n. *pulveris* of dust, referring to the source, house dust.

Acid-fast short rods or coccoid forms (<2.0 by approx. 0.5 µm). Does not form mycelia or branching. Abundant growth appears in 5 d at 37°C from dilute inocula on Ogawa egg medium. Colonies are wet, smooth, creamy or slightly yellowish, and non-photochromogenic. Strains grow in the presence of 5% (w/v) NaCl. The temperature range for growth is 28–42°C; occasional strains will grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: eight isolates were recovered from house dust from five houses in Obu, Aichi Prefecture, Japan.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35154, CCUG 37668, CIP 106804, DSM 44222, JCM 6370.

Sequence accession no. (16S rRNA gene): AJ429046.

Additional remarks: despite a rapid growth rate, this species demonstrates some characteristics typical of slow-growing mycobacteria and was considered to be intermediate between rapid and slow-growing species by Tsukamura et al. (1983a).

The *Mycobacterium peregrinum* clade

84. **Mycobacterium peregrinum** Kusunoki and Ezaki 1992, 244[VP]

pe.re.gri'num. L. neut. adj. *peregrinum* strange, foreign.

Acid-fast rods (1.5–4 × 0.5 µm). Colonies on egg medium appear in 7 d and are intermediate between smooth and rough, and white to slightly yellowish in color but non-photochromogenic. Temperature range for growth is 28–37°C; does not grow at 43°C. Growth occurs at 28 and 37°C on media supplemented with 5% (w/v) NaCl. However, on MacConkey agar growth occurs at 28°C, but not at 37°C. TLC of methanolysates shows the presence of α-, α'-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

This organism is a relatively rare cause of disease, but may do so in the same settings as *Mycobacterium fortuitum*.

Source: the type strain was isolated from bronchial aspirations from a Mexican child.

DNA G+C content (mol%): not determined.

Type strain: ATCC 14467, CCUG 27976, CIP 105382, DSM 43271, JCM 12142, NCTC 10264.

Sequence accession no. (16S rRNA gene): AF058712.

Additional remarks: this organism, proposed by Bojalil et al. (1962), was later considered to be synonymous with *Mycobacterium fortuitum* (Kubica et al., 1972; Minnikin et al., 1984; Pattyn et al., 1974; Stanford and Gunthorpe, 1969), hence its omission from the *Approved Lists of Bacterial Names* (Skerman et al., 1980). However, data from DNA–DNA relatedness studies (Baess, 1982; Lévy-Frébault et al., 1986b) supported the reintroduction of *Mycobacterium peregrinum* as a distinct species; Kusunoki and Ezaki (1992) formally proposed the reintroduction of the species. See also notes following the description of *Mycobacterium chelonae*.

85. **Mycobacterium wolinskyi** Brown, Springer, Steingrube, Wilson, Pfyffer, Garcia, Menendez, Rodriguez-Salgado, Jost, Chiu, Onyi, Böttger and Wallace 1999, 1508[VP]

wo.lins'ky.i. N.L. masc. gen. n. *wolinskyi* of Wolinsky, named for Emanuel Wolinsky for his significant contributions to the study of non-tuberculous mycobacteria.

Acid–alcohol-fast bacilli that produce smooth to mucoid off-white- to cream-colored colonies on Middlebrook 7H10 and trypticase soy agar after incubation for 2–4 d. Yellow/orange pigment is not produced. Growth occurs on MacConkey agar (without crystal violet) and in the presence of 5% (w/v) NaCl. The temperature range for growth is 30–45°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: initially isolated from a post-surgical facial abscess in Switzerland and identified as *Mycobacterium smegmatis* Group 3 (Pennekamp et al., 1997). An additional strain was isolated from a sternal wound infection following open heart surgery in Texas.

DNA G+C content (mol%): 68 ± 2 (HPLC).

Type strain: ATCC 700010, CCUG 47168, CIP 106348, DSM 44493, JCM 13393.

Sequence accession no. (16S rRNA gene): Y12873.

Additional remarks: this species was classified in an International Working Group on Mycobacterial Taxonomy (IWGMT) cooperative study designed to determine the degree of heterogeneity in the species *Mycobacterium smegmatis* (Brown et al., 1999). *Mycobacterium wolinskyi* has been implicated in post-traumatic wound infections.

86. **Mycobacterium mageritense** Domenech, Jimenez, Menendez, Bull, Samper, Manrique and Garcia 1997, 539[VP]

ma.ge.ri.ten'se. N.L. neut. adj. *mageritense* of or pertaining to *Magerit*, old (first) Arabic name of Madrid, the source of most of the isolates.

Strongly acid–alcohol-fast rods. Smooth, mucoid nonchromogenic colonies appear in 2–4 d on Löwenstein–Jensen medium. Strains grow on MacConkey agar (without crystal violet) and most, but not all, will tolerate 5% (w/v) NaCl. Temperature range for growth is 22–45°C; optimal growth range is 30–37°C. TLC of methanolysates shows the presence of α-, α'-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the original description was based on five strains isolated from sputum of different patients over a 2 year period. Subsequently, isolates were described from blood, bronchial washings, sinus drainage, and wound infections (Wallace et al., 2002). Two cases of furunculosis associated with contaminated footbaths attributed to the organism were described by Gira et al. (2004).

DNA G+C content (mol%): 67 ± 3 (HPLC).

Type strain: CIP 104973, ATCC 700351, CCUG 37984, DSM 44476, JCM 12375.

Sequence accession no. (16S rRNA gene): AY457076.

Additional remarks: see also description of *Mycobacterium cosmeticum*.

The *Mycobacterium sphagni* clade

87. **Mycobacterium sphagni** Kazda 1980, 81[VP]

sphag′ni. N.L. n. *Sphagnum* generic name of the moss of sphagnum bogs; N.L. gen. n. *sphagni* of *Sphagnum*.

Short, thick, often pleomorphic rods; usually clumped but not corded. Eugonic, smooth, glistening, orange-yellow scotochromogenic colonies are produced from dilute inocula on Löwenstein–Jensen and Middlebrook 7H10 agar media. Does not grow on MacConkey agar (without crystal violet) or in the presence of 3% (w/v) NaCl. The temperature range for growth is 22–37°C; optimal growth occurs at 31°C in 3 d and in less than 7 d at temperature extremes; does not grow at 45°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from sphagnum vegetation in moors of Germany and Scandinavia. No demonstrable virulence for rabbits, guinea pigs, or mice injected with 1–10 mg wet weight of cells.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33027, DSM 44076.

Sequence accession no. (16S rRNA gene): X55590.

Additional remarks: the uniqueness of the taxon is supported by skin testing of guinea pigs hyper-sensitized by injections of mycobacteria, by characteristic lipid patterns, and by immunodiffusion in agar (Kazda, 1980).

88. **Mycobacterium chlorophenolicum** (Apajalahti, Kärpänoja and Salkinoja-Salonen 1986) Häggblom, Nohynek, Palleroni, Kronqvist, Nurmiaho-Lassila, Salkinoja-Salonen, Klatte and Kroppenstedt 1994, 491[VP] (*Rhodococcus chlorophenolicus* Apajalahti, Kärpänoja and Salkinoja-Salonen 1986, 248)

chlo.r.o.phe.nol′i.cum. N.L. n. *chlorophenol* chlorophenol; L. neut. suffix *-icum* suffix used with the sense of pertaining to; N.L. neut. adj. *chlorophenolicum* related to chlorophenols.

Acid-fast rods in young cultures fragment into coccoid forms on further incubation. Optimum growth occurs at 28°C with the production of yellow to orange scotochromogenic colonies in 4–8 d. Temperature range for growth is 18–37°C; does not grow at 45°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: three strains of this species were independently isolated from chlorophenol-contaminated soil and sludge collected from different geographic locations in Finland.

DNA G+C content (mol%): 67.5–69.2 (HPLC).

Type strain: DSM 43826, ATCC 49826, CIP 104189, JCM 7439.

Sequence accession no. (16S rRNA gene): X79094.

Additional remarks: strains of this species were previously assigned to the genus *Rhodococcus* as *Rhodococcus chlorophenolicus* (Apajalahti et al., 1986). The species was transferred to the genus *Mycobacterium* (Häggblom et al., 1994) based on mycolic acid composition (Dobson et al., 1985), on the presence of *meso*-diaminopimelic acid, arabinose, and galactose in whole-organism hydrolysates, and 16S rRNA gene sequence data (Briglia et al., 1994)

89. **Mycobacterium chubuense** Tsukamura, Mizuna and Tsukamura 1981, 274[VP]

chu.bu.en′se. N.L. neut. adj. *chubuense* of or belonging to Chubu, coming from soil of Chubu hospital, Japan.

Acid-fast cocci in early stages of growth but acid-fastness may be lost on prolonged incubation. Smooth yellow colonies formed in 3 d on egg-based media. Temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows the presence of α-, α′-, and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from garden soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27278, CCUG 37670, CIP 106810, DSM 44219, JCM 6374, NCTC 10819.

Sequence accession no. (16S rRNA gene): X55596.

Additional remarks: the species was originally described by Tsukamura (1973) in Japanese, but was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980); the epithet was revived by Tsukamura et al. (1981).

90. **Mycobacterium poriferae** Padgitt and Moshier 1987, 189[VP]

po.ri.fe′ra.e. N.L. gen. *poriferae* of the Porifera, the phylum of sponges.

Gram-stain-positive, strongly acid–alcohol-fast rods (1.1–4.9 × 0.7–2.5 µm) which frequently appear coccoid. Non-dividing cells in cultures are typically 2.7–3.1 × 2.2–2.3 µm. Cells may become enlarged at one end and display an ovoid, non-acid-fast body, but neither branching nor Y-shaped cells occur. Visible growth appears on various media in 4 d, including Löwenstein–Jensen medium and Middlebrook 7H11 agar. Colonies are smooth, moist, shiny, and dome-shaped with a near-translucent apron which disappears on continued growth. Strains are scotochromogenic producing a strongly orange coloration. They tolerate a wide pH range (5.0–8.5) and will grow in the presence of 5% (w/v) NaCl. Temperature range for growth is 20–37°C; optimal growth occurs at 28–30°C; does not grow at 42°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from cell suspensions of a marine sponge.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35087, CIP 105394, JCM 12603.
Sequence accession no. (16S rRNA gene): AF480589.

91. **Mycobacterium psychrotolerans** Trujillo, Velázquez, Kroppenstedt, Shumann, Rivas, Mateos and Martínez-Molina 2004, 1461[VP]

psy.chro.to′le.rans. Gr. adj. *psuchros* cold; L. part. adj. *tolerans* tolerating; N.L. part. adj. *psychrotolerans* cold-tolerating.

Acid-fast, nonmotile, non-spore-forming, short rods. Smooth, entire, bright orange, scotochromogenic colonies are formed on glucose-yeast extract and nutrient agars after incubation for 2 d. Growth occurs on 5–7% (w/v) NaCl agar; is moderate on Löwenstein–Jensen medium, but growth does not occur on MacConkey agar. The temperature range for growth is 4–37°C. TLC of methanolysates shows the presence of α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the type strain was isolated from pond water near a uranium mine in Spain.
DNA G+C content (mol%): 64 (T_m).
Type strain: DSM 44697, JCM 13323.
Sequence accession no. (16S rRNA gene): AJ534886.

The *Mycobacterium parafortuitum* clade

92. **Mycobacterium parafortuitum** Tsukamura, Toyama and Mizuno 1965, 232[AL]

pa.ra.for.tui′tum. Gr. prep. *para* alongside of or near; L. neut. adj. *fortuitum* casual, accidental, and also a specific epithet; N.L. neut. adj. *parafortuitum* alongside of (*Mycobacterium) fortuitum*.

Rods (2–3 µm long). Creamy or pale yellow, smooth, moist colonies are formed from dilute inocula on Löwenstein–Jensen media and on agar media usually within 3–4 d. Pigment increases markedly in most strains with further incubation and after exposure to light. Tolerance to 5% (w/v) NaCl is variable. Temperature range for growth is 25–37°C; some strains grow well at 45°C. TLC of methanolysates shows α-, α′-, and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Injection of mice with 2 mg wet weight of cells did not cause any pathology and the organisms were rapidly eliminated.

Source: isolated from soil.
DNA G+C content (mol%): not determined.
Type strain: ATCC 19686, CCUG 20999, CIP 106802, DSM 43528, JCM 6367, NCTC 10411.
Sequence accession no. (16S rRNA gene): X93183.
Additional remarks: DNA–DNA homology studies (Baess, 1982) shows that *Mycobacterium parafortuitum* forms a distinct genospecies. It is most closely related to *Mycobacterium aurum* and *Mycobacterium vaccae*.

The taxon was first described by Tsukamura et al. (1965) and subsequently by Tsukamura (1966a). It was incorrectly cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980) as *Mycobacterium parafortuitum* Tsukamura (1966a) [see Hill et al. (1984)].

93. **Mycobacterium gilvum** Stanford and Gunthorpe 1971, 636[AL]

gil′vum. L. neut. adj. *gilvum* pale yellow.

Pleomorphic bacilli producing pale yellow, smooth colonies in less than 7 d on inspissated egg media. Grows at 25–37°C, but not at 45°C. The species was further characterized using numerical taxonomic data (Tsukamura et al., 1981). TLC of methanolysates shows α-, α′-, and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from sputum and pleural fluid but has not been isolated more than once from the same patient. It is not thought to be pathogenic.
DNA G+C content (mol%): 67.9 (whole-genome sequencing).
Type strain: ATCC 43909, CCUG 37676, CIP 106743, DSM 44503, JCM 6395, NCTC 10742.
Sequence accession no. (16S rRNA gene): X55599.

94. **Mycobacterium obuense** Tsukamura, Mizuno and Tsukamura 1981, 274[VP]

o.bu.en′se. N.L. neut. adj. *obuense* of or belonging to Obu, Japan.

Rods (2–6 µm), acid-fast in young cultures, but may lose some acid-fastness on prolonged culture. Dilute inocula on inspissated egg media yield smooth yellow-orange colonies in 5 d or less. The temperature range for growth is 25–27°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential features of the species are shown in Table 38.

Source: isolated from soil and from the sputum of one patient; not thought to be associated with disease.
DNA G+C content (mol%): not determined.
Type strain: ATCC 27023, CCUG 37669, CIP 106803, DSM 44075, JCM 6372, NCTC 10778.
Sequence accession no. (16S rRNA gene): X55597.
Additional remarks: this species was originally described by Tsukamura and Mizuno (1971), was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980) and was revived by Tsukamura et al. (1981).

The *Mycobacterium fortuitum* clade

95. **Mycobacterium fortuitum** da Costa Cruz 1938, 299[AL]

95a. **Mycobacterium fortuitum subsp. fortuitum** da Costa Cruz 1938, 299[AL]

for.tui′tum. L. neut. adj. *fortuitum* casual, accidental.

Acid-fast rods, 1–3 µm long; coccoid and short forms and some longer rods are seen, as are occasional beaded or swollen cells with non-acid-fast ovoid bodies at one end. Long filamentous branching forms are seen in pus. Acid-fastness varies from 10 to 100% of cells after incubation for 5 d at 28°C. Dilute inocula on Löwenstein–Jensen medium yield smooth, hemispheric colonies after incubation for 2–4 d. Colonies may be butyrous, waxy, multilobate, or even rosette-clustered; dull, waxy, rough colonies are also common. Colonies are usually off-white- or cream-colored, but when grown on malachite green-containing media, they may absorb the

green dye (Hartwig et al., 1962). Temperature range for growth is 22–42°C; does not grow at 45°C. Organisms grow at 28°C on MacConkey agar (without crystal violet) and in the presence of 5% (w/v) NaCl. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Generalized disease is rarely seen in most experimental animals, although localized kidney lesions are common in calves, guinea pigs, mice, monkeys, and rabbits; middle ear lesions lead to a characteristic "spinning disease" in mice (Penso et al., 1952; Wells et al., 1955). Some strains have been isolated from the lymph glands of cattle and systemic, nodular infections of frogs.

Source: strains were originally recovered from an injection site abscess and have been isolated from augmentation mammaplasties, endocarditis, local abscesses, meningitis, osteomyelitis, post-operative sternal wound infections, and pulmonary disease in humans. Also found in soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 6841, CCUG 20994, CIP 104534, DSM 46621, JCM 6387, NCTC 10394.

Sequence accession no. (16S rRNA gene): X52933.

Additional remarks: the valid publication of *Mycobacterium fortuitum* subsp. *acetamidolyticum* (Tsukamura et al., 1986c) automatically created *Mycobacterium fortuitum* subsp. *fortuitum* as a subspecies novum under Rule 40b of the Bacteriological Code (Tindall, 1999). Stanford and Gunthorpe (1969) found *Mycobacterium fortuitum* to be identical to Kuster's frog tubercle bacillus which was raised to species status as *Mycobacterium ranae* by Bergey et al. (1923) and proposed that by priority, *Mycobacterium ranae* should be the official name of the taxon. Runyon (1972) challenged the former name as a *nomen ambiguum* and, for stability in taxonomy, requested conservation of the epithet *fortuitum*, a request acceded to by the Judicial Commission of the International Committee on Systematic Bacteriology (1974).

Three subgroups or biovars of *Mycobacterium fortuitum* were described by Bönicke (1966) and further studied by Wallace et al. (1991). Subsequently, two biovars were assigned to distinct species status as *Mycobacterium fortuitum* and *Mycobacterium peregrinum*; the third biovariant complex, containing two unnamed taxa (sorbitol-positive and sorbitol-negative) remained unnamed (Wallace et al., 1991). The third biovar was subsequently found to contain significant heterogeneity and was the subject of polyphasic studies which resulted in proposals for four novel species, namely *Mycobacterium boenickei*, *Mycobacterium brisbanense*, *Mycobacterium houstonense*, and *Mycobacterium neworleansense* (see below; Schinsky et al., 2004).

95b. **Mycobacterium fortuitum subsp. acetamidolyticum** Tsukamura, Yano and Imaeda 1986a, 489[VP] (Effective publication: Tsukamura, Yano and Imaeda 1986c, 108.)

a.ce.ta.mi.do.ly′ti.cum. N.L. n. *acetamidum* acetamide; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *acetamidolyticum* digesting acetamide.

Acid-fast rods of a short or intermediate length (2–6 × 0.5–1 μm), which do not form cords. Colonies are rough, non-photochromogenic, and white in color after incubation at 37°C for 5 d on Löwenstein–Jensen or Ogawa egg media. The temperature range for growth is 22–42°C; does not grow at 45°C. Strains do not grow on MacConkey agar and do not tolerate 5% (w/v) NaCl. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from the sputum of a human patient; probably a lung pathogen.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35931, CIP 105423, DSM 44220, JCM 6368.

Sequence accession no. (16S rRNA gene): AF547923.

96. **Mycobacterium rhodesiae** Tsukamura, Mizuno and Tsukamura 1981, 274[VP]

rho.de.si′a.e. N.L. gen. n. *rhodesiae* of Rhodesia.

Very short rods (<2 μm). May lose acid-fastness on prolonged culture. Dilute inocula on egg and agar media yield brilliant yellow, smooth, moist colonies after incubation for less than 5 d. The temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

No demonstrable virulence for chickens, guinea pigs, mice, or rabbits.

Source: isolated from sputum samples from Rhodesian patients suspected to have tuberculosis. However, no positive evidence has emerged that the species is pathogenic for humans.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27024, CIP 106806, DSM 44223, JCM 6363, NCTC 10779.

Sequence accession no. (16S rRNA gene): AJ429047.

Additional remarks: originally described by Tsukamura et al. (1971), this species was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), but was revived by Tsukamura et al. (1981).

97. **Mycobacterium houstonense** Schinsky, Morey, Steigerwalt, Douglas, Wilson, Floyd, Butler, Daneshvar, Brown-Elliot, Wallace, McNeil, Brenner and Brown 2004, 1664[VP]

hous.ton.en′se. N.L. neut. adj. *houstonense* of or pertaining to Houston, Texas, USA, where the first isolate of the *Mycobacterium fortuitum* third biovariant (sorbitol-positive) was identified.

Pleomorphic acid-fast bacilli, often with long filamentous forms. Colonies on heart infusion agar supplemented with 5% (v/v) rabbit blood are white to slightly beige, mucoid, convex, round, and entire-edged. The temperature range for growth is 28–42°C. Growth occurs on Löwenstein–Jensen medium at 35 and 42°C after incubation for less than 7 d, but is microscopically visible as small (approx. 1 mm diameter) colonies after incubation for 2 d at 35°C. Growth occurs on MacConkey agar (without crystal violet) and 5% (w/v) NaCl agar at 28°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the type strain was isolated from a face wound.

DNA G+C content (mol%): 64 (T_m).

Type strain: ATCC 49403, DSM 44676.

Sequence accession no. (16S rRNA gene): AY012579.

Additional remarks: see remarks following the description of *Mycobacterium boenickei* and *Mycobacterium fortuitum*.

98. **Mycobacterium conceptionense** Adékambi, Stein, Carvajal, Raoult and Drancourt 2006b, 2025[VP] (Effective publication: Adékambi, Stein, Carvajal, Raoult and Drancourt 2006c, 1272.)

con.cep.tio.nen′se. N.L. neut. adj. *conceptionense* of or pertaining to Hôpital la Conception, the hospital where the first strain was isolated.

Gram-stain-positive, acid-fast bacilli. Colonies are nonpigmented and appear on 5% sheep blood agar, Middlebrook 7H10 agar, and Löwenstein–Jensen slants after incubation for 2–5 d. The temperature range for growth is 25–37°C; optimal growth is at 30°C; does not grow at 42°C. Tolerant of 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the species was isolated from tissue associated with post-traumatic osteitis, subsequent to an open tibia fracture in a 31-year-old woman who had endured an extended period in river water following an accident.

DNA G+C content (mol%): 64 ± 2 (HPLC).

Type strain: CIP 108544, CCUG 50187.

Sequence accession no. (16S rRNA gene): AY859684.

Additional remarks: in 16S rRNA gene sequencing studies, *Mycobacterium conceptionense* shows 99.7% similarity (4 bp difference) to *Mycobacterium porcinum* and 99.4% similarity (8 bp difference) to *Mycobacterium fortuitum*. The species has a similarities of 96.4% to *Mycobacterium porcinum* (15 bp difference) and 98.3% (7 bp difference) to *Mycobacterium fortuitum* based on *hsp65* gene sequences; similarities of 96.0 and 94.8%, respectively, based on *sodA* gene sequences and 95 and 94.8%, respectively, based on *recA* gene sequences. Sequencing of a 723 bp region of the *rpoB* gene shows *Mycobacterium conceptionense* to have 95.7% similarity to *Mycobacterium fortuitum* and 97% similarity to *Mycobacterium porcinum*.

99. **Mycobacterium senegalense** (Chamoiseau 1973) Chamoiseau 1979, 407[AL] (*Mycobacterium farcinogenes* subsp. *senegalense* Chamoiseau 1973, 220)

se.ne.gal.en′se. N.L. neut. adj. *senegalense* of or belonging to the West African Republic of Senegal.

Gram-stain-positive, strongly acid–alcohol-fast cells which form short or long, bent, and branched filaments. The latter are found in clumps or in a tangled lacy network and do not fragment into bacillary forms. This appearance does not change whether the organisms are seen in pus from lesions or smears from cultures. Colonies on Löwenstein–Jensen medium are non-chromogenic or ochre in color, rough and convoluted, firmly attached to the medium, and surrounded by an iridescent halo. In broth medium (tryptose broth with serum), a thick, rough, dry growth develops with a whitish surface veil, but the broth remains clear. Growth occurs in 1–2 d in liquid or on solid medium. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from lesions of farcy in African bovines. Strains produce a massive, generalized peritonitis in guinea pigs.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35796, CCUG 21001, CIP 104941, DSM 43656, NCTC 10956.

Sequence accession no. (16S rRNA gene): M29567.

Additional remarks: originally described as a subspecies of *Mycobacterium farcinogenes* Chamoiseau 1973 but was later recognized to be a totally different species on the basis of marked differences in growth rate, metabolic activities, lipid composition, and DNA homology (Baess, 1982; Chamoiseau, 1979). *Mycobacterium senegalense* is one of two acid-fast causative agents of farcy, a disease of the skin and superficial lymphatics in African bovines, the other being *Mycobacterum farcinogenes*. See also comments under the description of *Mycobacterium farcinogenes*.

100. **Mycobacterium farcinogenes** (Chamoiseau 1973) Chamoiseau 1979, 407[AL] (*Mycobacterium farcinogenes* subsp. *tchadense* Chamoiseau 1973, 220)

far.ci.no′ge.nes. Fr. n. *farcin* farcy or glanders; Gr. v. *gennaio* produce; N.L. adj. *farcinogenes* producing farcy.

Gram-stain-positive, strongly acid–alcohol-fast cells which form short or long, bent, and branched filaments. The latter are in clumps or in a tangled lacy network and do not fragment into bacillary forms. This appearance is shown in pus from lesions or smears from cultures. Colonies on Löwenstein–Jensen medium are honey yellow, rough and convoluted, firmly attached to the medium, and surrounded by an iridescent halo. In broth medium such as tryptose broth with serum, a thick rough dry growth develops with a whitish surface veil, but the broth remains clear. Growth occurs in 15–20 d in liquid or on solid medium. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Subcutaneous inoculation of the organism into guinea pigs produces draining abscesses after 8 d, which heal slowly. Six to 7 d after intraperitoneal injection of guinea pigs, abscesses are seen in the testes, seminal vesicles, or vagina; large abscesses are seen rarely in peritoneal walls and viscera; most animals die after prolonged infection.

Source: isolated from lesions of farcy in African bovines.

DNA G+C content (mol%): not determined.

Type strain: NCTC 10955, ATCC 35753, CCUG 21047, DSM 43637.

Sequence accession no. (16S rRNA gene): AF055333.

Additional remarks: a number of organisms isolated from lesions of bovine farcy were gathered into a group and designated *Nocardia farcinica*. Chamoiseau (1973) established that the agents of farcy in African bovines belonged in the genus *Mycobacterium*. At that time, he proposed the name *Mycobacterium farcinogenes*, subdividing the species into two subspecies, subsp. *tchadense* and subsp. *senegalense*. Subsequently, on the basis of marked differences in growth rate, metabolic activities, lipid composition, and DNA homology (Baess, 1982), he concluded that these taxa represented two distinct species, *Mycobacterium farcinogenes* and *Mycobacterium senegalense* (Chamoiseau, 1979). These species show a close relationship in 16S rRNA gene sequencing studies and differ from all other known mycobacteria in their occurrence in typical lesions in zebu cattle. See also the description of *Mycobacterium senegalense*.

101. **Mycobacterium septicum** Schinsky, McNeil, Witney, Steigerwait, Lasker, Floyd, Hogg, Brenner and Brown 2000, 580[VP]

sep′ti.cum. L. neut. adj. *septicum* producing a putrefaction, putrefying, septic, referring to the isolation of the organism from blood.

Gram-stain-positive, acid-fast, asporogenous, non-capsulated, pleomorphic coccobacilli. Longer filamentous forms are often observed, but true branching and aerial hyphae do not occur. Growth on Löwenstein–Jensen medium at 35°C produces cerebriform, slightly beige colonies with an irregular edge. Organisms grow at 28°C on MacConkey agar (without crystal violet) and on 5% (w/v) NaCl agar, but do not grow at 42 or 45°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a catheter tip and from the blood of a 2-year-old child with metastatic hepatoblastoma.

DNA G+C content (mol%): 64 (T_m).

Type strain: ATCC 700731, CCUG 43574, CIP 106642, DSM 44393.

Sequence accession no. (16S rRNA gene): AF111809.

102. **Mycobacterium alvei** Ausina, Luquin, García Barceló, Lanéelle, Lévy-Frébault, Belda and Prats 1992, 531[VP]

al′ve.i. L. gen. n. *alvei* of the bed of a river, referring to the place where this species was first isolated.

Short rods (1–3 × 0.5–0.7 µm), which frequently appear to be coccoid; strongly acid-fast, except for a small number (less than 10%) of cyanophil forms. Clumping of cells may occur, but there is no cord formation. Colonies on Löwenstein–Jensen medium and on Middlebrook 7H10 agar are eugonic, rough, and non-pigmented. The temperature range for growth is 25–37°C, with optimum growth at 30°C; does not grow at 45°C. Growth occurs after incubation for 5 d at 30°C, but at 37°C the organisms grow more slowly (10–15 d). Does not grow on MacConkey agar (without crystal violet) or on 5% (w/v) NaCl agar. TLC of methanolysates shows α- and ω-1 methoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the species description was based on six strains, three of which were isolated from water samples from the River Llobregat in Barcelona, two from human sputum samples, and the remaining one from soil.

DNA G+C content (mol%): not determined.

Type strain: CIP 103464, ATCC 51304, DSM 44176, JCM 12272.

Sequence accession no. (16S rRNA gene): AF023664.

103. **Mycobacterium porcinum** Tsukamura, Nemoto and Yugi 1983b, 164[VP]

por′ci.num. L. neut. adj. *porcinum* pertaining to swine.

Acid-fast rods (1.5–6 × 0.5 µm) with no cross-barring, cord formation, or mycelium production. Growth occurs after 3 d on egg-based media. Colonies are non-photochromogenic and on egg media are smooth to rough, but on agar media are dry and rough. The temperature range for growth is 28–42°C; does not grow at 45°C. The species is phenotypically similar to *Mycobacterium fortuitum* but lacks nitrate reductase, exhibits a positive succinamidase activity, and utilizes benzoate as a sole source of carbon. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: ten strains were recovered from the lymph nodes of swine having a tuberculosis-like lymphadenitis.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33776, CCUG 37674, CIP 105392, DSM 44242, JCM 6378.

Sequence accession no. (16S rRNA gene): AF480588.

104. **Mycobacterium boenickei** Schinsky, Morey, Steigerwalt, Douglas, Wilson, Floyd, Butler, Daneshvar, Brown-Elliot, Wallace, McNeil, Brenner and Brown 2004, 1664[VP]

bo.e.nic′ke.i. N.L. gen. masc. n. *boenickei* of Bönicke, in honor of the contribution of Rudolf Bönicke, a German microbiologist, who first recognized the heterogeneity within the *Mycobacterium fortuitum* complex.

Acid-fast pleomorphic bacilli, often with long filamentous forms. On heat infusion agar with 5% (v/v) rabbit blood, colonies are matt, white to slightly beige, domed, and scallop-edged. Aerial hyphae are not present. Small colonies (approx. 1 mm diameter) are visible microscopically after 2 d incubation at 35°C. Mature colonies on Löwenstein–Jensen medium at 35°C are visible in less than 7 d incubation. The temperature range for growth is 28–35°C; does not grow at 42°C. Growth occurs on MacConkey agar (without crystal violet) and 5% (w/v) NaCl agar at 28°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a leg wound.

DNA G+C content (mol%): 64 (T_m).

Type strain: ATCC 49935, DSM 44677.

Sequence accession no. (16S rRNA gene): AY012573.

Additional remarks: the unnamed third *Mycobacterium fortuitum* biovariant complex, containing two unnamed taxa (sorbitol-positive and sorbitol-negative), was first described by Wallace et al. (1991). Members of this biovariant complex frequently occur as human pathogens which cause skin and soft tissue abscesses with associated systemic involvement (Wallace et al., 1991; Wallace et al., 1983). Schinsky et al. (2004) carried out detailed genotypic and phenotypic analyses of clinical isolates formerly classified as the *Mycobacterium fortuitum* third biovariant complex, demonstrated significant heterogeneity, and proposed four novel species, namely *Mycobacterium boenickei*, *Mycobacterium brisbanense*, *Mycobacterium houstonense*, and *Mycobacterium neworleansense*.

105. **Mycobacterium neworleansense** Schinsky, Morey, Steigerwalt, Douglas, Wilson, Floyd, Butler, Daneshvar, Brown-Elliot, Wallace, McNeil, Brenner and Brown 2004, 1665[VP]

new.or.le.an.sen′se. N.L. neut. adj. *neworleansense* of or pertaining to New Orleans, Louisiana, USA, the source of the type strain.

Acid-fast pleomorphic bacilli, often with long filamentous forms. Colonies are white to slightly beige, rough, wrinkled, and irregular-edged on heart infusion agar supplemented with 5% (v/v) rabbit blood. The temperature range for

growth is 28–37°C; growth does not occur at 42°C. Growth occurs on Löwenstein–Jensen medium at 35°C after incubation for less than 7 d and is visible as small (approx. 1 mm diameter) colonies after incubation at 35°C for 2 d; it also grows on MacConkey agar (without crystal violet) and 5% (w/v) NaCl agar at 28°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: this species was described on the basis of a single strain isolated from a scalp wound.

DNA G+C content (mol%): 60 (T_m).

Type strain: ATCC 49404, DSM 44679.

Sequence accession no. (16S rRNA gene): AY012575.

Additional remarks: see comments following the descriptions of *Mycobacterium boenickei* and *Mycobacterium fortuitum.*

The *Mycobacterium neoaurum* clade

106. **Mycobacterium neoaurum** Tsukamura 1972a, 229[AL]

ne.o.au′rum. Gr. adj. *neos* new; L. n. *aurum* gold; N.L. n. *neoaurum* a new gold, intended to mean a new gold-pigmented organism.

Intermediate to long rods. Golden yellow colonies are visible after incubation for less than 5 d on inspissated egg media. The temperature range for growth is 25–37°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from soil and not known to be related to human disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 25795, CCUG 37665, CIP 105387, DSM 44074, JCM 6365, NCTC 10818.

Sequence accession no. (16S rRNA gene): M29564.

Additional remarks: an original description in Japanese (Tsukamura, 1972a) was followed by a more detailed description in English (Tsukamura et al., 1981).

107. **Mycobacterium brisbanense** Schinsky, Morey, Steigerwalt, Douglas, Wilson, Floyd, Butler, Daneshvar, Brown-Elliot, Wallace, McNeil, Brenner and Brown 2004, 1665[VP]

bris.ban.en′se. N.L. neut. adj. *brisbanense* of or pertaining to Brisbane, Queensland, Australia, the source of the type strain.

Acid-fast, pleomorphic bacilli, often with long filamentous forms. Colonies are white to slightly beige, mucoid, convex, round, and entire-edged on heart infusion agar supplemented with 5% (v/v) rabbit blood; growth is visible as small (approx. 1 mm diameter) colonies after incubation for 2 d at 35°C. Growth occurs on MacConkey agar (without crystal violet), on 5% (w/v) NaCl agar at 28°C, and on Löwenstein–Jensen medium at 35°C after incubation for less than 7 d. The temperature range for growth is 28–37°C; does not grow at 42°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the species was described on the basis of a single strain isolated from an antral sinus.

DNA G+C content (mol%): 62 (T_m).

Type strain: ATCC 49938, CCUG 47584, DSM 44680.

Sequence accession no. (16S rRNA gene): AY012577.

Additional remarks: see comments following the descriptions of *Mycobacterium boenickei* and *Mycobacterium fortuitum.*

108. **Mycobacterium frederiksbergense** Willumsen, Karlson, Stackebrandt and Kroppenstedt 2001, 1719[VP]

fre.de.riks.ber.gen′se. N.L. neut. adj. *frederiksbergense* of or belonging to Frederiksberg, Denmark, referring to the place of isolation.

Gram-stain-positive, acid-fast, nonmotile, short rods; coccoid elements occur. Colonies are smooth, cadmium yellow, and scotochromogenic after incubation for 5 d on trypticase soy broth and Middlebrook 7H10 agar. The temperature range for growth is 15–37°C; optimal growth occurs at 30°C. Does not grow on MacConkey agar. Degrades polycyclic aromatic hydrocarbons. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from the site of a former gas works at Frederiksberg, Denmark.

DNA G+C content (mol%): not determined

Type strain: DSM 44346, CIP 107205.

Sequence accession no. (16S rRNA gene): AJ276274.

109. **Mycobacterium fluoranthenivorans** Hormisch, Brost, Kohring, Giffhorn, Kroppenstedt, Stackebrandt, Farber and Holzapfel 2006, 1459[VP] (Effective publication: Hormisch, Brost, Kohring, Giffhorn, Kroppenstedt, Stackebrandt, Farber and Holzapfel 2004, 659.)

flu.o.ran.the.ni.vo′rans. N.L. n. *fluoranthenum* fluoranthene; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *fluoranthenivorans* fluoranthene devouring, a property of the organism.

Gram-stain-positive, acid–alcohol-fast, nonmotile rods (2 × 1 μm), which are non-chromogenic. Grows rapidly within a temperature range of 20–37°C, but does not grow at 42°C. Metabolizes fluoranthene but not other polycyclic aromatic hydrocarbons. TLC of methanolysates shows α-, α′-, and epoxy-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from polycyclic aromatic hydrocarbon-polluted soil from a former coal gas plant, using a complex liquid medium.

DNA G+C content (mol%): not determined.

Type strain: DSM 44556, CIP 108203.

Sequence accession no. (16S rRNA gene): AJ617741.

110. **Mycobacterium diernhoferi** Tsukamura, van der Meulen and Grabow 1983c, 468[VP]

di.ern.ho′fer.i. N.L. gen. masc. n. *diernhoferi* of Diernhofer, who originally isolated the organisms.

Acid-fast rods (2–6 × 0.5 μm). Colonies are smooth, white, and nonphotochromogenic after incubation for 3 d at 28 and 37°C. Does not grow at 42°C. Susceptible to $NH_2OH.HCl$ (250 μg/ml) and ethambutol (5 μg/ml), but is resistant to isoniazid (10 μg/ml), rifampin (25 μg/ml), and thiophene-2-carboxylic acid hydrazide (1 μg/ml). Reduces nitrate but is negative in the 3 d arylsulfatase test. Grows in media supplemented with 5% (w/v) NaCl.

TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: strains were recovered from soil in a cattle field and are not known to be associated with human disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 19340, CIP 105384, DSM 43524, JCM 6371.

Sequence accession no. (16S rRNA gene): X55593.

Additional remarks: the species was originally described by Bönicke and Juhasz (1965), was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), but was revived by Tsukamura et al. (1983c).

111. **Mycobacterium canariasense** Jiménez, Campos-Herrero, García, Luquin, Herrera and García 2004, 1733[VP]

ca.na.ri.a.sen′se. N.L. neut. adj. *canariasense* of or belonging to the Canarias (the Spanish name of the Canary Islands), where all strains were isolated.

Partially acid-fast rods. Colonies are smooth, moist, shiny, and non-pigmented after incubation for 2–3 d on Löwenstein–Jensen medium. The temperature range for growth is 30–37°C; does not grow at 22, 42, or 45°C. Growth occurs on MacConkey agar (without crystal violet), but not on agar supplemented with 5% (w/v) NaCl.

Strains are positive for arylsulfatase activity (3 d) and Tween 80 hydrolysis, produce a low level of heat-stable catalase, and are negative for nitrate reduction. TLC of methanolysates shows α- and α′-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from blood samples of patients suffering from a febrile illness considered to be nosocomially acquired, possibly as a result of venous catheterization.

DNA G+C content (mol%): not determined.

Type strain: CCUG 47953, CIP 107998.

Sequence accession nos: AY255478 (16S rRNA gene); AY255477 (*hsp65*).

Additional remarks: on the basis of the presence of two operons in the genome and a short helix 18, this species belongs to the II-s mycobacterial class proposed by Menendez et al. (2002).

112. **Mycobacterium cosmeticum** Cooksey, de Waard, Yakrus, Rivera, Chopite, Toney, Morlock and Butler 2004, 2390[VP]

cos.me′ti.cum. N.L. neut. adj. *cosmeticum* referring to cosmetics.

Acid-fast rods (approx. 1.5 × 0.55 μm) which rarely form cell aggregates in liquid culture. Colonies have smooth surfaces and edges, and are domed and scotochromogenic, with a pale yellow coloration on Löwenstein–Jensen medium and on Middlebrook 7H10 agar. Growth from dilute inocula appears after 3 d incubation on Löwenstein–Jensen medium at 28–37°C; does not grow at 45°C. Grows on MacConkey agar (without crystal violet), but not on media supplemented with 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the type strain was isolated from a granulomatous lesion of a female patient in Venezuela who was undergoing mesotherapy. Three further strains were isolated from footbath drains and a sink at a nail salon located in Atlanta, Georgia, USA (Gira et al., 2004).

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-878, CIP 108170.

Sequence accession nos: AY449728 (16S rRNA gene); AY449730 (*hsp65*).

Additional remarks: the association of rapidly growing mycobacteria with furunculosis resulting from cosmetic nail treatments has been repeatedly reported; see also the description of *Mycobacterium mageritense* and Withrop et al. (2002).

The *Mycobacterium mucogenicum* clade

113. **Mycobacterium mucogenicum** Springer, Böttger, Kirschner and Wallace 1995a, 266[VP]

mu.co.gen′i.cum. L. n. *mucus* mucus, Gr. v. *gennaio* to produce; L. neut. suff. *-icum* suffix used with the sense of pertaining to; N.L. neut. adj. *mucogenicum* intended to mean producing mucus, referring to the highly mucoid character of most strains on solid agar.

Gram-stain-positive, acid–alcohol-fast, asporogenous, curved bacilli. Visible growth appears on Middlebrook 7H10 and trypticase soy agars in 2–4 d. Colonies are usually smooth, off-white in color, mucoid, and non-pigmented. Growth occurs (although poorly at times) on MacConkey agar (without crystal violet), but not in the presence of 5% (w/v) NaCl. The temperature range for growth is 28–37°C; does not grow at 42°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: originally recovered from outbreaks of peritonitis associated with automated peritoneal dialysis machines and the tap water used to supply the machines. Subsequently, isolates of this species have commonly been involved in water-borne nosocomial outbreaks. *Mycobacterium mucogenicum* has been associated with some incidents of post-traumatic wound infection and catheter-related sepsis (Wallace et al., 1993). The type strain was recovered from a human neck abscess.

DNA G+C content (mol%): not determined.

Type strain: ATCC 49650, CCUG 47451, CIP 105223, DSM 44625, JCM 13575.

Sequence accession no. (16S rRNA gene): AY457074.

Additional remarks: since many characteristics of the isolates were similar to those of *Mycobacterium chelonae*, isolates of *Mycobacterium mucogenicum* were tentatively designated *Mycobacterium chelonae*-like organisms (MCLO) by Silcox et al. (1981).

114. **Mycobacterium aubagnense** Adékambi, Berger, Raoult and Drancourt 2006a, 140[VP]

au.bag.nen′se. N.L. neut. adj. *aubagnense* of or pertaining to Aubagne, the city from which the first patient originated.

Gram-stain-positive, acid-fast bacilli. Colonies are non-pigmented and appear on 5% sheep blood and Middlebrook 7H10 agars and on Löwenstein–Jensen medium after incubation for 2–5 d. The temperature range for growth is 24–37°C; optimal growth occurs at 30°C; does

not grow at 42°C. Does not grow on media supplemented with 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a bronchial aspirate of a patient with chronic pneumonia.

DNA G+C content (mol%): 63–65 (HPLC).

Type strain: CIP 108543, CCUG 50186.

Sequence accession nos: AY859683 (16S rRNA gene); AY859689 (*recA*); AY859677 (*hsp65*); AY859707 (*sodA*).

Additional remarks: in 16S rRNA and *rpoB* gene sequence studies, this species shows similarities of 99.1% and 92.7%, respectively to *Mycobacterium mucogenicum*. Other genetic regions (*hsp65*, *sodA*, and *recA*) show considerable diversity within the same species. The taxon is described as a distinct species on the basis of *rpoB* gene sequence variation. See also descriptions of *Mycobacterium bolletii* and *Mycobacterium phocaicum*.

115. **Mycobacterium phocaicum** Adékambi, Berger, Raoult and Drancourt 2006a, 140[VP]

pho.ca′i.cum. L. neut. adj. *phocaicum* Phocoean, referring to Phocaea, a maritime town of Ionia, a colony of the Athenians, whose inhabitants fled to escape from Persian domination and founded Massilia (Marseille), which was the source of the type strain.

Gram-stain-positive acid-fast bacilli. Colonies are nonpigmented and appear on 5% (v/v) sheep blood and Middlebrook 7H10 agars, and Löwenstein–Jensen medium after incubation for 2–5 d. The temperature range for growth 24–37°C; optimal growth occurs at 30°C; does not grow at 42°C. Does not grow in media supplemented with 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: the type strain was isolated from a bronchial aspirate; two other strains have been isolated from patients with chronic pneumonia.

DNA G+C content (mol%): not determined.

Type strain: CIP 108542, CCUG 50185.

Sequence accession nos: AY859682 (16S rRNA gene); AY859688 (*recA*); AY859676 (*hsp65*); AY859706 (*sodA gene*).

Additional remarks: this species shows 100% 16S rRNA gene and 95.0% *rpoB* gene sequence similarity to *Mycobacterium mucogenicum*. The taxon was described as a distinct species on the basis of *rpoB* gene sequence data. See also descriptions of *Mycobacterium aubagnense* and *Mycobacterium bolletii*.

The *Mycobacterium chelonae* clade

116. **Mycobacterium chelonae** corrig. Bergey, Harrison, Breed, Hammer and Huntoon 1923, 376[AL]

che.lo′na.e. Gr. fem. n. *chelone* a tortoise; N.L. gen. n. *chelonae* of a tortoise.

Cells are pleomorphic rods, ranging from long and narrow to short and thick (1–6 × 0.2–0.5 µm), with coccoid forms (0.5 µm) also reported. In cultures less than 5-d-old, organisms are strongly acid-fast; thereafter, non-acid-fast forms begin to develop. Colonies may be smooth, moist, and shiny or rough. They are usually nonchromogenic to creamy buff in color and are produced from dilute inocula after incubation for 3–4 d on most media. Though the temperature range for growth is 22–40°C, some strains of *Mycobacterium chelonae* may not grow (or may grow poorly) at temperatures of 37°C or higher; does not grow at 42°C. TLC of methanolysates shows α- and α′-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: although rarely isolated from sputum, this species has caused cervical adenitis, corneal infections, prosthetic valve endocarditis, and wound infections (including post-operative infections). It is also found in soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35752, CCUG 47445, CIP 104535, DSM 43804, JCM 6388, NCTC 946.

Sequence accession no. (16S rRNA gene): AF480594.

Additional remarks: originally proposed as *Mycobacterium chelonei* for Friedmann's turtle tubercle bacillus, but it was noted that, given the gender of the binomial name for the turtle, the correct name for this organism is *Mycobacterium chelonae* (Hill et al., 1984; von Graevenitz and Berger, 1980). Several studies have confirmed the distinction of this species from closely related rapid-growing mycobacterial species (Jenkins et al., 1971; Stanford and Beck, 1969; Stanford et al., 1972), while others have suggested that this species is synonymous with *Mycobacterium abscessus* and "*Mycobacterium borstelense*" (Kubica et al., 1972; Stanford and Beck, 1969; Stanford et al., 1972). In contrast, cooperative numerical taxonomic studies showed *Mycobacterium abscessus* to differ in some features from *Mycobacterium chelonae* and "*Mycobacterium borstelense*" (Kubica et al., 1972; Saito et al., 1977). Kubica et al. (1972) proposed two subspecies, the taxonomic integrity of which was supported by subsequent studies (Silcox et al., 1981; Tsukamura, 1981). Baess (1982) reported that *Mycobacterium chelonae* subsp. *abscessus* ATCC 19977[T] and *Mycobacterium chelonae* subsp. *chelonae* ATCC 19235 were closely related, as the two strains showed 99% DNA homology. However, strain ATCC 19235 is not the type strain of *Mycobacterium chelonae* subsp. *chelonae* and a more comprehensive DNA–DNA relatedness study, which included the type strain of *Mycobacterium chelonae* subsp. *chelonae* ATCC 35752[T], was carried out by Lévy-Frébault et al. (1986b) who concluded that the two taxa should be viewed as independent species. Kusunoki and Ezaki (1992) formally proposed the re-establishment of *Mycobacterium abscessus* as a distinct species.

117. **Mycobacterium abscessus** Kusunoki and Ezaki 1992, 244[VP]

abs.ces′sus. L. gen. n. *abscessus* of an abscess, referring to the ability of the organism to form abscesses.

Acid-fast rods (1.0–2.5 × 0.5 µm). Colonies on egg medium appear in 7 d, are intermediate between smooth and rough, and are white to gray in color and non-photochromogenic. The temperature range for growth is 28–37°C; does not grow at 43°C. On MacConkey agar and on media containing 5% (w/v) NaCl, growth occurs at 28°C and at 37°C. TLC of methanolysates shows α- and α′-mycolates. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: originally isolated from the synovium of the knee and associated gluteal abscesses of a patient. Causes wound and soft tissue infections, but is also found in soil.

DNA G+C content (mol%): 64.1 (T_m).

Type strain: ATCC 19977, CCUG 20993, CIP 104536, DSM 44196, JCM 13569, NCTC 13031.

Sequence accession no. (16S rRNA gene): X82235.

Additional remarks: see notes following description of *Mycobacterium chelonae*. This species was described originally by Moore and Frerichs (1953), but was not cited on the *Approved Lists of Bacterial Names* (Skerman et al., 1980).

118. **Mycobacterium immunogenum** Wilson, Steingrube, Böttger, Springer, Brown-Elliot, Vincent, Jost, Zhang, Garcia, Chiu, Onyi, Rossmoore, Nash and Wallace 2001, 1762[VP]

im.mu.no′gen.um. N.L. neut. adj. *immunogenum* eliciting an immune response.

Gram-stain-positive, acid–alcohol-fast, asporogenous, curved bacilli. Visible growth appears on Middlebrook 7H10 and trypticase soy agars in less than 7 d. Colonies are non-pigmented, off-white in color, and rough, although smooth forms may occur. Growth occurs on MacConkey agar (without crystal violet), but not in media supplemented with 5% (w/v) NaCl. The temperature range for growth is 30–35°C; optimal growth is at 30°C; does not grow at 45°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Isolates of this species, along with strains of *Mycobacterium abscessus* and *Mycobacterium chelonae*, have commonly been involved in water-borne nosocomial outbreaks and pseudo-outbreaks. However, *Mycobacterium immunogenum* is clearly incriminated in hypersensitivity pneumonitis associated with metalworking fluid (Fraser et al., 1992; Kreiss and Cox-Ganser, 1997; Shelton et al., 1999). The species has also been identified as a cause of keratitis following laser *in situ* keratomileusis (Sampaio et al., 2006).

Source: the type strain was isolated from a sample of bronchoscope wash water.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700505, CCUG 47286, CIP 106684.

Sequence accession no. (16S rRNA gene): AY457080.

Additional remarks: phenotypic separation of *Mycobacterium immunogenum* from *Mycobacterium abscessus* and *Mycobacterium chelonae* is difficult and identification of this species is primarily based on 16S rRNA gene sequence data. Additionally, *Mycobacterium immunogenum*, unlike *Mycobacterium abscessus* and *Mycobacterium chelonae*, does not contain a single rRNA operon.

119. **Mycobacterium bolletii** Adékambi, Berger, Raoult and Drancourt 2006a, 140[VP]

bol.let′i.i. N.L. gen. masc. n. *bolletii* of Bollet, to honor Claude Bollet, a famous clinical microbiologist and taxonomist.

Gram-stain-positive, acid-fast bacilli. Colonies are non-pigmented and appear on 5% (v/v) sheep blood and Middlebrook 7H10 agars, and on Löwenstein–Jensen medium after incubation for 2–5 d. The temperature range for growth is 24–37°C; optimal growth occurs at 30°C; does not grow at 42°C. Strains do not grow on media supplemented with 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from sputum.

DNA G+C content (mol%): not determined.

Type strain: CIP 108541, CCUG 50184.

Sequence accession nos: AY859681 (16S rRNA gene); AY859687 (*recA*); AY859675 (*hsp65*); AY862403 (*sodA*).

Additional remarks: this species shows 100% 16S rRNA gene and 95.6% *rpoB* gene sequence similarity to *Mycobacterium abscessus*. The taxon is described as a distinct species on the basis of *rpoB* gene sequence data. See also descriptions for *Mycobacterium aubagnense* and *Mycobacterium phocaicum*.

120. **Mycobacterium massiliense** Adékambi, Reynaud-Gaubert, Greub, Gevaudan, La Scola, Raoult and Drancourt 2006b, 2025[VP]

mas.si.li.en′se. L. neut. adj. *massiliense* pertaining to *Massilia*, Latin name of Marseille, where the organism was isolated.

Gram-stain-positive, acid-fast, nonmotile, and asporogenous rods. Strictly aerobic. Colonies on 5% (v/v) sheep blood agar are non-photochromogenic and intermediate between smooth and rough. Growth occurs after incubation for 2–4 d on 5% (v/v) sheep blood and Middlebrook 7H10 agars, and on Löwenstein–Jensen medium. The temperature range for growth is 24–37°C; optimal growth occurs at 30°C; does not grow at 42°C. Growth occurs on MacConkey agar (without crystal violet) and on Löwenstein–Jensen medium supplemented with 5% (w/v) NaCl. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from the sputum and bronchoalveolar lavage of a patient with hemoptoic pneumonia.

DNA G+C content (mol%): 65 ± 3 (HPLC).

Type strain: CIP 108297, CCUG 48898.

Sequence accession nos: AY593980 (16S rRNA gene); AY596465 (*hsp65*); AY593975 (*sodA*); AY593979 (*recA*); AY593981 (*rpoB*); AY593978 (ITS).

Additional remarks: this species was initially proposed by Adékambi et al. (2004) and the name was validly published in Validation List no. 111 (Adékambi et al., 2006b). The 16S rRNA gene sequence of *Mycobacterium massiliense* shows complete identity with that of *Mycobacterium abscessus* (1483 bp). The 441-bp region of the *hsp65* gene described by Telenti et al. (1993), and a partial 441-bp region of the *sodA* gene differed by 5 and 3 nucleotides, respectively, from the corresponding sequences of *Mycobacterium abscessus*. Partial *recA* and *rpoB* gene sequence analyses showed 98% and 96% similarity, respectively, to *Mycobacterium abscessus*. 16S–23S rRNA ITS sequence analysis showed that *Mycobacterium massiliense* differed from *Mycobacterium abscessus* by one substitution and a single insertion.

121. **Mycobacterium salmoniphilum** Whipps, Butler, Pourahmad, Watral and Kent 2007, 2529[VP]

sal.mo.ni′phi.lum. L. n. *salmo -onis* a salmon; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. neut. adj. *salmoniphilum* salmon-loving.

Acid-fast bacilli, slender, straight or slightly curved (1–4 × 0.25–0.6 µm), with occasional short and thicker forms. Colonies are cream-colored, smooth, and shiny after incubation for 4–6 d on Middlebrook 7H10 agar and on Löwenstein–Jensen slants. Growth also occurs on MacConkey and blood agars. After prolonged incubation (more than 10 d), colonies may be waxy, with an irregular border and a "fried egg" appearance. The temperature range for growth is 20–30°C, with weak or delayed growth at 10°C; does not grow at 37°C. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolates were recovered from the viscera (predominantly the kidney) of infected salmonid fish.

DNA G+C content (mol%): not determined.

Type strain: ATCC 13758, DSM 43276.

Sequence accession nos: DQ866768 (16S rRNA gene); DQ866777 (*hsp*65); DQ866790 (*rpoB*).

Additional remarks: originally described by Ross (1960), this species was not cited in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), but was revived by Whipps et al. (2007). Gene sequence analyses show a close relationship between *Mycobacterium salmoniphilum* and members of the *Mycobacterium chelonae* complex.

Single-membered 16S rRNA gene clades

122. **Mycobacterium hassiacum** Schröder, Naumann, Kroppenstedt and Reischl 1997, 90[VP]

has.si.a′cum. M.L. neut. adj. *hassiacum* of or belonging to *Hassia*, the German province of Hesse, where the organism was first isolated.

Partially acid-fast rods which are longer and thinner following growth at higher temperatures. Colonies are 2–5 mm in diameter, smooth, and scotochromogenic after incubation for 2–3 d on Löwenstein–Jensen medium. Growth occurs on MacConkey agar (without crystal violet) and on media supplemented with 5% (w/v) NaCl. In dense growth, colonies are slimy, but when grown at 40–65°C, they are distinct and drier. The temperature range for growth is 30–65°C; higher temperatures seem to favor growth. TLC of methanolysates shows α-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from urine on a single occasion; not thought to be pathogenic.

DNA G+C content (mol%): 65.8 (HPLC).

Type strain: DSM 44199, CCUG 37519, CIP 105218, JCM 12690.

Sequence accession no. (16S rRNA gene): U49401.

Additional remarks: Schröder et al. (1997) noted that while this organism displayed rapid growth and has the molecular signature of a rapidly growing species, it appeared to be phylogenetically nearer to the slow-growing species *Mycobacterium xenopi*. This conclusion is borne out by 16S rRNA gene sequence data (Figure 86).

123. **Mycobacterium madagascariense** Kazda, Müller, Stackebrandt, Daffé, Müller and Pitulle 1992, 526[VP]

mad.a.gas.car.i.en′se. N.L. neut. adj. *madagascariense* of or belonging to the island of Madagascar, the source of the strains.

Gram-stain-positive, acid–alcohol-fast, polymorphic rods (1.2–1.5 × 0.6 µm) which often form clumps, but not cords or cross bands. Colonies from dilute inocula on Löwenstein–Jensen medium and Middlebrook 7H10 agar are 1–2 mm in diameter, eugonic, smooth, and glistening with yellow or orange pigmentation. Growth occurs after 3 d at 31°C and after 7 d at 22°C; does not grow at 37°C. Does not grow on MacConkey agar or on media supplemented with 5% (w/v) NaCl. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Strains are not pathogenic for guinea pigs, mice, or rabbits.

Source: isolated from sphagnum vegetation in Madagascar.

DNA G+C content (mol%): not determined.

Type strain: ATCC 49865, CIP 104538, JCM 13574.

Sequence accession no. (16S rRNA gene): X55600.

124. **Mycobacterium moriokaense** Tsukamura, Yano and Imaeda 1986b, 335[VP]

mo.ri.o.ka.en′se. N.L. neut. adj. *moriokaense* of or belonging to Morioka, the locality where the species was first isolated.

Acid-fast, asporogenous, nonmotile rods (2–6 × 0.5 µm), which do not form cords. Colonies on Löwenstein–Jensen medium and on Ogawa egg medium are dry, rough, and non-pigmented after incubation for 3 d at 28–42°C. Does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from the sputum of a patient with tuberculosis. However, this species is common in soil and is unlikely to be a human pathogen.

DNA G+C content (mol%): not determined.

Type strain: ATCC 43059, CCUG 37671, CIP 105393, DSM 44221, JCM 6375.

Sequence accession no. (16S rRNA gene): AJ429044.

125. **Mycobacterium gadium** Casal and Rey Calero 1974, 306[AL]

ga′di.um. L. gen. pl. n. *gadium*, of *Gades* (the modern Cadiz, a town on the Atlantic coast of Spain).

Gram-stain-positive, acid–alcohol-fast, short rods. Colonies on Löwenstein–Jensen medium are small, butyrous, and spherical after incubation for 3–4 d; yellow, scotochromogenic pigmentation increases slightly on exposure to light. Colonies become dry, rugged, and flat in older cultures. The temperature range for growth is 28–37°C; does not grow at 45°C. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Intraperitoneal injection of large numbers of the organism into guinea pigs and mice produced local

lymphadenopathy in 2 weeks, with some dissemination into nearby organs, but this process resolved in 8 weeks. Not likely to be pathogenic for humans.

Source: isolated from the sputum of a patient in whom an *Mycobacterium tuberculosis* infection was later diagnosed.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27726, CCUG 37515, CIP 105388, DSM 44077, JCM 12688, NCTC 10942.

Sequence accession no. (16S rRNA gene): X55594.

126. **Mycobacterium hodleri** Kleespies, Kroppenstedt, Rainey, Webb and Stackebrandt 1996, 686[VP]

hod'le. ri. N.L. gen. masc. n. *hodleri* of Hodler, referring to Christian Hodler, director of the Ministry of Science and Culture of the State of Lower Saxony, Germany, a strong supporter of natural sciences.

Gram-stain-positive, acid-fast, asporogenous, nonmotile rods (1.8–2.3 × 1 μm). Some cells appear as V-forms and in palisades. Colonies are smooth, but with some rough variants, and are saffron yellow and scotochromogenic after incubation for 4–5 d on trypticase soy broth and Middlebrook 7H10 agars. The temperature range for growth is 18–28°C; optimal growth is at 25°C. Degrades polycyclic aromatic hydrocarbons. TLC of methanolysates shows α- and keto-mycolates, and wax esters. Differential characteristics of the rapidly growing species are shown in Table 38.

Source: isolated from a fluoranthene-contaminated site near Jülich, Germany.

DNA G+C content (mol%): 73 (HPLC).

Type strain: DSM 44183, CIP 104909, JCM 12141.

Sequence accession no. (16S rRNA gene): X93184.
